LIST OF CONTRIBUTORS TO VOL. XLIX.

- ABBE, Dr. ROBERT, New York.
 ADAMI, Dr. J. GEORGE, Montreal, Canada.
 AGRAMONTE, Dr. ARISTIDES, New York.
 ALEXANDER, Dr. E., Paso del Norte, Mexico.
 ALLEN, Dr. CHARLES W., New York.
 AMBLER, Dr. C. P., Canton, O.
 BARBOUR, Dr. LLEWELLYN P., Tullahoma, Tenn.
 BARKAN, Dr. L., Brooklyn, N. Y.
 BARUCH, Dr. SIMON, New York.
 BECK, Dr. CARL, New York.
 BELL, Dr. E. L., North Woodstock, N. H.
 BELL, Dr. T. J., Tyler, Texas.
 BERG, Dr. HENRY W., New York.
 BERKLEY, Dr. HENRY J., Baltimore, Md.
 BERNAYS, Dr. A. C., St. Louis, Mo.
 BEVILL, Dr. CHEVES, Winfield, Ark.
 BILLINGS, Dr. JOHN S., Jr., New York.
 BIRD, Dr. V. S., Tampa, Fla.
 BISHOP, Dr. LOUIS FAUGÈRES, New York.
 BOEKER, Dr. HERMANN, New York.
 BORCK, Dr. EDWARD, St. Louis, Mo.
 BORDEN, Dr. W. C., U. S. Army.
 BOYD, Dr. E. G., Leadville, Col.
 BOYD, Dr. ROBERT, Grand Cayman, Jamaica, W. I.
 BOYLAND, Dr. HALSTED, Paris, France.
 BRANNAN, Dr. JOHN WINTERS, New York.
 BRIDGES, Dr. WILLSON O., Omaha, Neb.
 BRYANT, Dr. JOSEPH D., New York.
 BULKLEY, Dr. L. DUNCAN, New York.
 BURDETT, Mr. HENRY C., London.
 CANTRELL, Dr. J. ABBOTT, Philadelphia, Pa.
 CANTWELL, Dr. FRANK V., Trenton, N. J.
 CARLUCCI, Dr. FRANCESCO, New York.
 CARPENTER, Dr. ALFRED C., New York.
 CARTER, Dr. E. C., U. S. Army.
 CAVERLY, Dr. C. S., Rutland, Vt.
 CHASE, Dr. WALTER B., Brooklyn, N. Y.

THYROTOMY; WITH REPORT OF A SERIES OF CASES OPERATED UPON DURING THE PAST TWENTY YEARS.¹

By CLINTON WAGNER, M.D.,

SENIOR SURGEON METROPOLITAN THROAT HOSPITAL, NEW YORK CITY.

THYROTOMY, or laryngotomy, as it was formerly termed, was first proposed by Desault about a century ago, although he never had occasion to perform it. To Bauers, of Louvain, is due the honor of having been the first to perform it. Gurdon Buck, of this city, did it in 1851, his being the third case on record. Dr. Sands and Dr. Gouley, also of this city, performed it early in the '60's.

The introduction of the laryngoscope into general practice, by which the cause of laryngeal obstruction to respiration can easily be diagnosed, caused the operation to grow rapidly into favor with surgeons. I think it may safely be assumed that it was performed in many cases by those engaged in general surgery, in which a skilled laryngoscopist might have operated by the intra-laryngeal method. In fact, thirty years ago, a contention arose between Dr. Morell Mackenzie and Mr. Durham, of Guy's Hospital, as to which was the preferable method for removing laryngeal growths, thyrotomy or the intra-laryngeal method through the mouth.

It is not my purpose to discuss the relative merits of the two methods. The immense number of cases of growths that have been successfully removed *per vias naturales*, without involving life, settles the question as to the superiority of that method.

But there are two classes of cases in which thyrotomy will always be justifiable, if not absolutely necessary. First malignant growths, for which the radical surgical treatment must be either thyrotomy or excision of half or the entire larynx; secondly, cases of occlusion of the larynx in very young children, such as I will describe later on. I shall endeavor to show that although thyrotomy is not always a simple, easy operation, still it is not dangerous to life if carefully performed, neither is it necessarily destructive to the vocal function in non-malignant cases.

In performing the operation, the shoulders of the patient should be well raised, and the head thrown back, by which the skin covering the larynx is made tense, and that organ thrown prominently forward. An incision should then be made through the skin and fascia from a little above the thyroid notch downward, in the median line to the cricoid. With a small probe-pointed knife, the crico-thyroid membrane is divided, and then with a gentle sawing motion the knife is carried upward through the thyroid cartilage. In young persons the section is made without difficulty, but in middle-aged or old persons ossification of the thyroid will have taken place, to divide which, the saw must be employed. I use a small file-cut saw

wheel, made to revolve by means of the electric motor. The section can be made in an incredibly short space of time. The incision is clean and can be maintained in the median line without difficulty. Malgaigne says of this operation, "ossification of the thyroid renders it absolutely impossible." But in his time the electric motor did not form a part of the surgeon's armamentarium. The difficulties of the operation begin as soon as the larynx is penetrated. The introduction of the knife, together with the flow of blood, produce violent reflex action. The larynx rises and falls spasmodically and very rapidly. The employment of a sharp-pointed knife or scissors, at this stage of the operation, is highly fraught with danger. During the rapid movements of the larynx, its posterior wall might be penetrated, and thus cause a laryngo-oesophageal fistula. At this moment, the operator has need of all his coolness and presence of mind. During the spasmodic action of the larynx, in spite of all that may be done to prevent it, a certain amount of blood will find its way down the trachea and into the lungs. If the patient is not fully under the influence of the anæsthetic (and he should not be), it will excite further reflex action. Violent coughing will follow, and the blood will be expelled.

I am always extremely careful in regard to the amount of anæsthetic administered. Coughing, under these circumstances, may be regarded as a danger signal. In deep or complete anæsthesia it will not take place. The blood will collect, and death on the table from asphyxia may suddenly take place.

The divided edges of the thyroid should now be kept widely apart by retractors, the anæsthetic carefully pushed, and the removal of the growth, false membrane, or whatever the cause of the laryngeal occlusion may be, proceeded with. Except in cancerous growths the hemorrhage usually is not very great. In all my operations I have never found it necessary to apply a ligature. Gentle compression has always been sufficient to arrest the bleeding, and I cannot conceive where a distinguished laryngologist, Fauvel of Paris, placed thirty-eight ligatures in one of his thyrotomies, and I am not surprised that he should denounce it as "a severe and bloody operation." The only artery that lies in the course of the surgeon's knife is the crico-thyroid, which is very small and can easily be secured by compression. No evil effects follow the division of the cricoid cartilage. I usually cut down to the cannula in the trachea, in order to gain more room. The cannula may be removed during the operation, if it is in the way, and it generally is. Silver sutures, as recommended by the earlier operators, passed through the thyroid for the purpose of maintaining the divided edges of the cartilage in apposition after the operation, are quite unnecessary. If the skin is brought together by a few sutures, aided by plaster, it will maintain the edges of the thyroid in firm apposition.

Thyrotomy is not an operation for the display of brilliancy and dash on the part of the surgeon. It is a tedious operation in which, in order to secure safety, celerity should not be attempted. The larynx of a child under five years of age is extremely small, the opening made for the play of instruments still

¹ Read before the New York Academy of Medicine, Section Laryngology and Rhinology, November 27, 1895.

smaller, which, with the flow of blood and the rapid spasmodic movements of the larynx, tend to obscure the landmarks, and tax to the utmost the patience of the surgeon and his assistants.

I have performed thyrotomy on five adults and five very young children. My youngest subject was eighteen months old, my oldest sixty-six and a half years. Upon one of the adult cases I subsequently operated four times, and upon another a second operation was performed, both being for the removal of recurrent malignant growths. If I include these operations, the total number of thyrotomies I have performed will amount to fifteen. In none of these cases of malignant growth was the operation in any way responsible for the death of the patient. They all survived the operation several months. With the exception of two, all the cases have been reported. I will, therefore, refer to them in as brief a manner as possible. The two that have not as yet been published I shall give more in detail.

CASE I.—Epithelioma.—Mr. C—, aged forty-seven, consulted me in October, 1875. There was a large sessile growth on the right vocal cord, covering the middle and extending into the anterior third. I removed all that could be seized with the forceps; very little remained and his voice was greatly improved. In November, 1876, he called for an examination of his throat. Recurrence had taken place, but he did not care to have treatment resumed just at that time. In June, 1877, the stenosis was very great, producing an alarming dyspnoea. Tracheotomy was performed at the Metropolitan Throat Hospital, followed immediately by thyrotomy. In consequence of the small breathing-space, no ether was administered until the cannula had been introduced. The growth was found to extend downward to the cricoid cartilage. It was thoroughly removed, the cord destroyed, and the galvano-cautery freely applied to the attachments of the growth. Recurrence took place at intervals of a few months. Thyrotomy was performed in all five times. He died in June, 1879, nearly four years after he first came under my treatment.

I might mention that the operations subsequent to the first thyrotomy were not performed with any expectation, on my part, of a radical cure, but at the solicitation of the patient, who declared that they gave him relief from suffering. The hemorrhage accompanying the curetting was always very profuse.

CASE II.—Papilloma Recurring as an Epithelioma.—Consulted me in January, 1881, at which time there was a growth on the right cord near the anterior commissure. I regarded it as a papilloma and suggested removal by forceps, which could have been done without difficulty. The patient declined operative interference and sought treatment elsewhere. Twelve months later he again consulted me, at which time the whole box of the larynx was almost completely filled with the growth. Several large pieces were removed by means of the forceps, but as it was found to extend downward below the cricoid cartilage, and as dyspnoea was becoming more urgent each day, tracheotomy and thyrotomy were performed, the growth removed, and the patient discharged in a few weeks from the hospital. The tumor was submitted to Dr. Heitzman, of this city, for examination, who pronounced it a papilloma. But in his report he stated that it had grown from a highly inflamed base, and if it recurred it would most likely come as a malignant growth. A few months later, in June, just before I left for Europe the patient came to me, suffering from great dyspnoea. A large amount of growth had reappeared in the larynx, on the right side. During my absence a cannula was introduced into his trachea by a surgeon in Brooklyn; and upon my return I again operated. This time I removed an enormous amount of growth.

It involved the whole of the right side of the larynx, and extended below the cricoid cartilage. Its attachments were destroyed by the galvano-cautery. A portion of the tumor which was submitted to Dr. Heitzman for microscopic examination, was pronounced to be epithelioma. Recurrence took place four months later. I then excised the entire right half of the larynx. The patient died fifteen days after this operation.

CASE III.—Epithelioma.—J. D—, aged forty-eight years. Case presented no unusual features; tracheotomy and thyrotomy were performed at the Metropolitan Throat Hospital; thyroid found to be ossified. Growth was thoroughly removed and the patient left the hospital in two weeks in good condition. Recurrence took place within four weeks and the patient died three months after the operation.

CASE IV.—Ecchondrosis.—J. H—, aged thirty; Irish; consulted me at the Metropolitan Throat Hospital, at the suggestion of Dr. Moore, of Troy. About a year previous tracheotomy had been performed for laryngeal dyspnoea, which had suddenly become alarming; since then has worn the cannula; has had syphilis.

An examination revealed a large rounded mass on the left side of the larynx, just anterior to the left arytenoid, and filling almost its entire cavity. I performed thyrotomy, and found that the tumor grew from the thyroid, very hard and firm, and, without doubt, of the very rare variety known as an ecchondrosis. I could make no impression upon it, either with gouge or knife, and attempts at removal brought on violent paroxysms of spasmodic coughing, although the patient was fully under the influence of ether.

I saw and examined him about fourteen months after the operation; apparently no change had taken place.

CASE V.—Epithelioma or Papilloma?—E. F—, aged sixty-four and a half years, applied for treatment at the Metropolitan Throat Hospital in April, 1893. Stated that about a year previous he began to grow hoarse, and have difficulty in breathing. On the left side of the larynx, involving the entire vocal cord and the ventricular band, was a large growth which produced considerable stenosis, although respiration was fairly good. There was considerable infiltration of the submucous tissue. As there was a history of syphilis, contracted some thirty years ago, I decided to give him the benefit of the doubt and accordingly gave him the proper remedies; but no appreciable effect was produced, and the treatment was discontinued. In September, having caught a slight cold, the dyspnoea became so severe and urgent that in my absence Dr. Hope performed tracheotomy. Later on he removed a portion of the growth with the forceps and submitted it to a microscopist for examination, who reported it to be a typical epithelioma. As the patient seemed comfortable and in excellent health, and was, moreover, disinclined to submit to a radical operation, it was decided to do nothing. I saw the patient at long intervals, but about fifteen months after the cannula had been introduced I was struck with the appearance of the growth. Instead of having increased, it had apparently diminished in size. This was probably owing to the disappearance of the submucous infiltration. The man's general condition was excellent, no engorgement of the cervical lymphatics, and the growth presented very much the appearance of a papilloma. The patient was very anxious to dispense with the cannula, if possible. I proposed a thyrotomy, and explained to him that in case there was no recurrence of the growth, I would remove the cannula. The thyroid was ossified, or rather eburnified. The circular saw, propelled by the electric motor, went through it very rapidly. The growth was thoroughly removed by means of curette

and forceps, and the galvano-cautery applied to its attachments. The mass removed was submitted to another microscopist, who pronounced it a papilloma. The patient rallied nicely from the effects of the operation, and left the hospital ten days after it was performed. He wore a tightly fitting cork in the orifice of the cannula, and breathed without difficulty through his larynx. He frequently urged me to remove the cannula. About ten weeks after the operation he suddenly expired at his residence of some acute pulmonary trouble. He had not been at the hospital for a week before his death. When I last saw him, about nine weeks after the operation, no recurrence of the growth had taken place. An autopsy was refused by his friends. He was sixty-six and a half years old at the time of performing the thyrotomy.

CASE VI.—Georgie, aged five years, was admitted into the Metropolitan Throat Hospital February 3, 1879, suffering from alarming dyspnoea, with frequent attacks of spasm of the glottis. An examination revealed a large papilloma attached to the right cord and almost completely filling the box of the larynx, and between the cords posteriorly could be distinctly seen what appeared to be a web of membrane stretched from cord to cord. As the child was greatly reduced in flesh and strength, thyrotomy was at once decided upon. Tracheotomy was first performed, followed immediately by the thyrotomy. The growth was removed, the membranous web cut away with the scissors, and the patient put to bed. The membranous web was the result of an attack of diphtheria or croup which he had had some months before. The boy recovered perfectly and gained rapidly in strength and flesh; was discharged from the hospital five weeks after the operation. This patient, operated upon nearly seventeen years ago, was exhibited at the meeting. Voice excellent.

CASE VII.—A boy between three and four years of age was attacked with diphtheria at the New York Foundling Asylum in November, 1882. Tracheotomy was performed by Dr. G. M. Swift, at that time house surgeon of the institution. The child recovered from the diphtheria, and in due time an attempt was made to dispense with wearing the cannula. Dyspnoea followed and the tube was reinserted. Numerous attempts were subsequently made with the same result. Five months after the tracheotomy was performed I was requested to give my opinion as to the cause of dyspnoea upon removing the cannula. Owing to the resistance made by the child, I was unable to obtain a very satisfactory view of the larynx. I gave as my opinion that there was laryngeal obstruction, probably a membranous web, the result of the ulceration of diphtheria. I suggested thyrotomy and was requested to take charge of the case and perform the operation. I found below the vocal cords and just above the inferior border of the thyroid a membranous web stretched across the larynx and occluding at least the anterior two-thirds of its lumen. This was removed carefully by means of scissors and knife, after which I had no difficulty in carrying my index finger through the glottis into the mouth. The wound healed kindly, twelve days after the operation; the cannula, which he had worn for nearly six months, was removed. Two years later the child, well and strong, with a good strong voice, was sent from the asylum to a home in the West which had been provided for him.

Sister M. Irene, founder of the New York Foundling Hospital, writing to me under date of November 19, 1895 (twelve and a half years after the operation), says, "His voice is clear and strong and his throat healthy, never having experienced any difficulty in breathing, etc."

CASE VIII.—A girl child, aged three years, was

admitted into the Metropolitan Throat Hospital in April, 1884, suffering from alarming dyspnoea with frequent attacks of spasm of the glottis, caused by a large papilloma attached to the left vocal cord. Tracheotomy was performed, but during the operation a large vein was cut, which bled profusely; the prostration from hemorrhage was so great that I was compelled to defer thyrotomy for two weeks; it was then performed in the usual manner. The patient was discharged from the hospital at the expiration of two months, but attended my clinic as an out-door patient, and was kept under observation for six months longer.

I saw this girl about ten days ago, eleven and a half years since the operation. Her voice is good, loud, and distinct, but modified. There is a small granulation at the anterior commissure in the line of my incision, the removal of which with the forceps will greatly improve her voice.

CASE IX.—A child, boy, aged eighteen months, I was requested to take charge of while at Colorado Springs. Dyspnoea began about three months before I saw it, following exposure to wet and cold. Spasms of the glottis were frequent, especially during the night, and were most alarming in their intensity. There was complete aphonia. An examination with the mirror was impossible. Merely approaching the child caused it to struggle, and in its struggles spasm of the glottis was invariably brought about.

Carefully observing the child when quiet and undisturbed by excitement, I became satisfied that the obstruction to respiration was laryngeal and not thoracic. I performed tracheotomy and immediately upon the introduction of the cannula the relief in respiration was quite apparent. On account of the extremely weak condition from long deprivation of a proper air supply, I decided to postpone the thyrotomy until it had improved in health and strength. Two weeks later I performed thyrotomy and upon the left vocal cord posteriorly I found quite a large papilloma which I removed. The wound healed kindly, and in about ten days after the operation the parents were compelled to return to their home and declined to leave the child in the hospital, promising, however, to return with it at an early day. I instructed the father to insert, a month after the operation, a tightly-fitting cork into the cannula in order that respiration might be carried on through the larynx. I was absent from Colorado for many months and upon my return I wrote the father to bring the boy to me. In his reply to my letter he stated that the child was in excellent health, that he breathed without difficulty through the mouth and nose, and that voice was returning to him. He named an early day on which he would bring him to me. A few days later he again wrote, stating that the little fellow had just died, eleven months after the operation, after a brief illness from the gripe, which at the time was very prevalent throughout Colorado.

CASE X.—Mary M.—, aged three years and seven months, was admitted into the Willard Parker Hospital on June 2, 1895, suffering from diphtheria. An intubation tube had been introduced six days before admission. On July 13th it became necessary to perform tracheotomy. The larynx seemed to be occluded and the cannula was worn continuously.

The above is an abstract of the report of the case furnished me by Dr. W. L. Somerset, resident physician at the Willard Parker Hospital. On October 14th she was sent to the Metropolitan Throat Hospital for surgical treatment. At that time she was in an extremely feeble condition, and very much reduced in flesh. In fact I desisted in my effort to make a laryngoscopic examination on account of her weak condition. I obtained, however, a good but momentary view of the epiglottis and the region immediately be-

low it. The aperture of the larynx seemed to be completely obliterated. Two days after admission ether was administered through the cannula, and the operation performed in the usual manner, by an incision from the thyroid notch downward through the cricothyroid membrane, which was afterward extended through the cricoid to the cannula. An extraordinary condition was encountered. The entire lining membrane of the larynx, from the epiglottis to the cricoid cartilage, appeared to be thickened and covered with a mass of what seemed to be granulations. After removing a portion with the scissors and forceps, an attempt was made to pass an ordinary laryngeal silver sound upward and forward into the mouth, but without success. It encountered an obstinate resistance. Upon carrying the index finger of my left hand into the mouth, and below the epiglottis, I could distinctly feel the point of my sound below this dense mass of adventitious tissue, and finally I succeeded with the aid of the knife and my finger in forcing an opening sufficiently large to permit the sound to pass through into the mouth. Further efforts enabled me to force a dilator through, and to enlarge gradually the opening. As much of the tissue as I could reach I cut away. The lower part of the canal was also cleared out as thoroughly as possible. Fearing, from this unusual condition, that complete occlusion of the canal might again result if I brought the divided edges of the thyroid together, the entire cavity was packed with iodoform gauze which was daily renewed, the dilator frequently passed upward into the mouth, and granulations removed by the curette from time to time. On the nineteenth day after the operation the gauze was permanently removed, and the external wound closed in the usual manner, the cannula being allowed to remain.

At the present time the child's general condition is excellent, she being fat and strong. The external wound has closed, a very fair amount of air passes through the larynx, and from time to time a tightly-fitting cork is inserted into the orifice of the cannula and the little patient is thus compelled to breathe through her nose and mouth. The voice is returning, and from present appearances and indications I shall be able before a great while to remove the cannula.

Casts in Non-Albuminous Urine.—Dr. A. Kossler has examined the urine of twenty-nine patients for casts, there being no albumin in any of the cases. In eighteen out of the twenty-nine cases, hyaline and granular casts were found, and in a few cases epithelial ones also. Cases of pulmonary phthisis showed the largest number of casts. While none of the specimens of urine contained serum albumin, most of them yielded nucleo-albumin, in varying quantity. In a number of cases Dr. Kossler had opportunities to make post-mortem examinations of these cases of nucleo-albuminuria, with casts. In none of them were there any well-marked inflammatory changes in the kidneys. He found, however, some changes in the epithelium of the urinary tubules, showing various stages of necrobiosis of the cells.

Tuberculosis.—Dr. Ingraham regards the fever thermometer as an ideal instrument in the diagnosis of suspected cases of tuberculosis. He feels sustained in the assertion that a rise of temperature of from one-half to one degree at some period of greater or less duration every twenty-four hours, may be regarded as the first symptom of pulmonary tuberculosis. Also that this rise of temperature, as a rule, occurs previous to every other symptom, and before the general health of the individual is influenced to a noticeable degree. —INGRAHAM.

THE LAW OF LIBEL AND SLANDER, AS AFFECTING MEDICAL PRACTITIONERS.¹

By W. A. PURRINGTON,

NEW YORK.

JOB and Dogberry wished to be libelled. Dogberry, that he might have an action for damages; Job, that he might answer the charge against him; for the desire of the man of Uz that his accuser might write a book, was but a call for the indictment against him, so that, knowing the specific accusation, he might the better "maintain his ways." In ecclesiastical and admiralty courts the first pleading, which sets out the cause of action, was the book, *librum*, *libellum*, or libel. In common law the word came to mean any communication, otherwise than by oral speech, unjustifiably accusing private individuals, officials, or governments of anything tending to make them ridiculous or injure them in reputation or public esteem. Slander, on the other hand, is a statement by word of mouth, unjustifiably imputing to a person either crime punishable at law, a contagious disease of a nature to exclude him from society, incapacity, or lack of integrity in the discharge of an office of profit; or else something that either naturally tends to injure him in his business, or actually has occasioned special and provable damage to him. The distinction between the two classes of defamation is generally ignored by laymen; it is too little borne in mind often by lawyers and sometimes even judges in their reasonings; and occasionally, on the other hand, it is emphasized to the point of hair-splitting. Libel is an indictable crime. Slander is not. The reason generally assigned for this difference, that the former more than the latter tends to cause breach of the peace, is obviously as inadequate as is the modern punishment of criminal libel, which is usually a small fine, although imprisonment is sometimes meted out, as recently in the District of Columbia, where one Moreno was imprisoned ninety days for defaming the Italian envoy. A better ground for the distinction is the deliberate evil intent and far-reaching consequences of written, as contrasted with oral, vilification. Because one is disposed to resent a truthful rather more than a false accusation, the maxim grew up in criminal law, "The greater the truth the greater the libel." And even now, when, as a general rule, truth of the publication may be pleaded as justification in both civil and criminal suits for defamation, yet in the criminal action it must appear that the publication was not only true, but also made with good motive. But although in the criminal action fuller justification is required, and conviction thus made easier, still the punishment is so inadequate that redress for libel is almost always sought, as in case of oral slander it must be sought, in civil courts.

Examples will best show the difference between oral and written defamation. In New York, adultery is not a crime, although forbidden by the Decalogue; therefore, an oral charge of that offence against Jones, a player or lawyer, is not slander, and might even flatter a wanton youth; but as against Jones, a clergyman, the same words would be actionable, from their tendency necessarily to injure him in his holy office; while the like accusation against a physician has been said to be no slander, unless, perhaps, the co-respondent named were a patient, in which case the charge, probably, would be slanderous.² So, too, in those States where adultery is a crime, a false charge of this nature would be slanderous, if orally made of any one; and the like accusation, if written, becomes libellous even where there is no statute in aid of the seventh commandment, by force of its ten-

¹ A paper read before the Society of Medical Jurisprudence, in New York City, on December 9, 1895.

² *Avre vs. Craven*, 2 Ad. and E., 2.

dency to hold up the accused to scorn and injure him in public esteem. Again, to say that Brown, an attorney, has certified to the efficacy of Blowhard's Unfailing Remedy, charges the man of law with no unprofessional conduct and is not slander. But a statement that Brown, a physician, has puffed the nostrum, probably would be adjudged defamatory,¹ such puffing being not only contrary to medical custom and tradition, but a violation of the laws of medical societies, for which a member may be expelled.²

It is difficult to assent to the application of general principles to facts in some of the cases. The principle is well settled that any words imputing general professional ignorance or malpractice to a physician are actionable *per se*—that is to say, without proof of special damage. But merely to say that a physician in a particular case has been mistaken, or insufficiently careful, or might have managed it better, is not slanderous, unless resulting damages be proved; for all men are liable to error. Thus, in an old English case,³ in the time of Charles I., the slanderous words alleged were: "Thou art a drunken fool and an ass: thou wert never a scholar, and art not worthy to speak to a scholar; and that I will prove and justify." Defendant's counsel urged that these words were not actionable, "fool and ass" being merely terms of scorn, while the other words touched plaintiff only in his scholarship and not in his art, since "a physician may be no good scholar, and yet a good physician." The chief justice was also, at first, of that opinion, but took the point under advisement; and, finally, it was adjudged for plaintiff, on the ground that "no man could be a good physician unless he be a good scholar." It may well be doubted whether to say that a physician is no scholar would constitute slander to-day. And in a somewhat doubtful Pennsylvania case, holding it no slander to say of a physician, "If he is a twopenny bleeder, I am none. I am a regular physician and no quack," it was held that this old English case did not apply in a community where many physicians held no diplomas, and college graduation was not essential to medical repute and right to practise.⁴

What statements relating to the medical conduct of a case constitute slander, was thoroughly discussed in an action brought in Connecticut early in the century.⁵ Dr. Sumner had been unfortunate, as we all may be in our cases. As a man-midwife he had attended Mrs. Phœbe Johnson, brought to bed of twins. Her first child was born dead, the other died within two days, and the mother followed them within a fortnight. He also attended Mrs. Haynes, but for what ailment the record does not disclose. One Utley said of Sumner's treatment of Mrs. Johnson: "He has killed three and ought to be hung, damn him. They all died through his mismanagement. I have understood he left the after-birth; and a man that would do that ought to be hung, damn him." And to Mrs. Haynes Utley said of Sumner: "He was the means of your sickness, by cutting an artery in your head. Damn him, you ought not to pay him a cent. If Mr. Haynes had took him up for it, it would have cost him \$400. It ought to be put in the newspapers." The jury found a verdict for plaintiff in the sum of \$600, no inconsiderable amount for the time and locality. A new trial was asked, on the ground that the expressions complained of only alleged malpractice in particular cases, and no special damage was alleged or proved. But the verdict was sustained, and the correct principle in such cases stated to be that "The misrepresentation of a physician's

practice, in a particular case, if it does not warrant the presumption of damages, is not actionable, unless special damages are alleged and proved; but if, from the nature of the calumny, damages are inferable, the words are actionable *per se*." All the judges agreed as to this governing principle, but differed in its application; for one dissenting judge could find nothing generally slanderous in these words, while his colleagues, although admitting that mistaken conduct in a particular case might be consistent with great knowledge, skill, or care in general, since any physician might err in diagnosis or judging the effect of drugs, were yet of opinion that to charge a surgeon with opening an artery by mistake for a vein, or a man-midwife with leaving the after-birth, was to make an accusation which, if believed, necessarily implied such gross ignorance as would prevent the public from employing the accused, and so injure him professionally. The chief justice said: "As a general principle it can never be admitted that the practice of a physician or surgeon in a particular case may be calumniated with impunity unless a special damage is shown. By confining the slander to particulars, a man may thus be ruined in detail: a calumniator might follow the track of the plaintiff and begin by falsely ascribing to a physician the killing of three persons by mismanagement, and then the mistaking of an artery for a vein, and thus might proceed to misrepresent every single act of his practice, until his reputation should be blasted beyond remedy." This seems to be good sense, and has been approved since as good law. Somewhat later another and similar case¹ arose in Connecticut. For some reason Dr. Camp ceased to attend a patient, and one Martin availed himself of the occasion to say, if Dr. Camp had "continued to treat her, she would have been in her grave before this time; his treatment of her was rascally." The physician sued and won a verdict. Still Martin prevailed eventually; for the court arrested judgment, thus reasoning: Except for the word "rascally," the expression conveyed no imputation on the plaintiff incompatible with his being a practitioner of general skill and learning, and perfect integrity; the term "rascally," however, in connection with the other words, "certainly implies that there was mismanagement of some kind on the part of the plaintiff in the treatment of the case;" but, nevertheless, as the nature of that mismanagement does not appear, it cannot be said that the charge necessarily affects plaintiff's general reputation for medical knowledge, skill, and care; and no special damage was shown. But the doctrine of Sumner *vs.* Utley was expressly approved. That doctrine was early accepted in a New York case,² growing out of the following remarks by a certain Mr. Harris: "Dr. Secor killed my children. He gave them teaspoonful doses of calomel and they died." "Dr. Secor gave them teaspoonful doses of calomel and it killed them; they did not live long after they took it. They died right off, the same day." The trial court—following an older New York case³ which held it no slander to say of an attorney, "Foot knows nothing about the suit and he will lead you on until he has undone you," and a medical case in Queen Elizabeth's time,⁴ holding it not actionable to say that a physician killed a patient with physic, since he might have done this involuntarily, through not knowing the disease—considered the words of Harris not slanderous, and said, with unpleasant frankness, "There is no physician, however eminent, who is not liable to mistake the

symptoms of a particular disease; nor any attorney who may not misunderstand the complicated nature and legal consequences of a particular litigation." But Dr. Secor appealed, and the appellate court, pronouncing the doctrine of *Foot vs. Brown* unsound, and approving *Sumner vs. Utley*, decided the words of Harris to be slanderous *per se*. So, too, in an Alabama case it was held actionable to say of a doctor, "He has killed the child, by giving it too much calomel."¹

In England it has been said that, while it was not slander to say of an apothecary, "He made up the medicines wrong, through jealousy, because I would not allow him to use his own judgment," there being no suggestion that injury resulted from the medicine, yet the words, "He killed my child; it was the saline injection that did it," would give a cause of action.² And, in Indiana, it was held that, although the words, "In my opinion, the bitters that Diver fixed for Smith were the cause of his death," since they impute neither crime nor general incompetency, were not actionable, yet a cause of action did arise upon the words, "The bitters that Dr. Diver gave to John Smith caused his death. There was poison enough in them to kill ten men;" for they constituted an allegation of gross incompetency.³ Long ago it was considered slanderous in England to say of an apothecary, "It is a world of blood he has to answer for in this town through his ignorance; he did once kill a woman and two children at Southampton; he did kill John Prior at Petersfield." "He was the death of John Prior; he has killed his patients with physick."⁴ And two hundred and fifty years ago, Mr. Ockham paid damages to Apothecary Davis for saying of him, "That knave Davis, the apothecary, hath poisoned my uncle; I will have him digged up again and hang him."⁵

After Southee, a surgeon and accoucheur, had safely delivered a patient, defendant said to her in the presence of others: "I wonder you had him to attend you! Do you know him? He is not an apothecary; he has not passed any examination; he is a bad character; none of the medical men here will meet him. Several persons have died that Mr. Southee has attended, and there have been inquests held on them." Southee brought an action, but alleged no special damages; and defendant contended that the holding of an inquest did not impute lack of skill in the surgeon. But the court held that the words were actionable, and inclined to believe that they were so, even apart from the statement as to inquests, and that the words, "He is a bad character; none of the medical men here will meet him," were slanderous.⁶ But where an action was brought upon words charging a physician with meeting homœopaths in consultation, innuendo that in consequence regular practitioners would not meet him, the words were held to be not slanderous.⁷

Sometimes the *odium medicum*—a survival, perhaps, of the *odium theologicum* from the time when priest and physician were one—finds expression in condemning the unorthodox rather than his doctrine; and then lawyers may reap a profit. Thus the poor opinions held and frankly expressed of one another by Drs. Carroll and White, in the quiet town of Amsterdam, have served to illumine this dark province of the law. Dr. White took occasion to say: "Dr. Carroll has killed six children in one year. Dr. Carroll and the other physicians of the village have killed seventy in one year." Now, Amsterdam is comparatively a small place, and these large mortality statistics may be

taken *cum grano salis*, when it is understood that Dr. White, although reared in the faith, had gone over to the doctrines and practice of homœopathy. However that may be, Dr. Carroll brought his action of slander; but neglect to plead that the regular practice of medicine was the weapon hinted at as used by him in slaughtering the six innocents, almost lost him his case; for the court held that, as the killings were not attributed to his ignorance, lack of skill, or misconduct, the charge did not affect him professionally. But, on the other hand, the judges declined to consider the word "killed" in *mitiori sensu*, as was the old rule laid down in *Poe vs. Mendford*—already referred to as holding that the involuntary killing of patients is consistent with eminent medical attainments—and held, on the contrary, that as the charge of killing six children could be fairly understood as imputing, at least, manslaughter, if not murder in the first degree, it slandered plaintiff as a citizen, if not as a physician.⁸ Thus Carroll triumphed. But his turn generally comes to the patient man. In course of time Mr. Jay Phillips, falling into his last illness, called upon Dr. White to help him homœopathically, and then upon Dr. Carroll to aid him in orthodox wise. Both physicians were in vain; and the patient, dying, left a will as his contribution to the support of the legal profession. Dr. Carroll being called before the surrogate to testify as to the mental capacity of testator, was asked if any other physician had attended decedent. Here was his opportunity to give slur for slur, at least so a jury thought. He answered: "Not as I know of, not as I know of. I understand he had a quack; I would not call him a physician. I understand that Dr. White, as he is called, had been there." Here, in turn, was Dr. White's chance to go to law, and he went there, getting a verdict of \$100. Dr. Carroll, claiming that his words as a witness were privileged, took the case to the court of appeals, but all the courts held that privilege attached to his testimony only while given in a *bona fide* belief in its pertinency and relevancy; but if the jury believed, as they had a right to do, that defendant answered maliciously and only to defame his adversary, they were entitled to find the verdict against him.⁹ This was White's victory; and by this case it was finally settled in the State of New York that it is slander to call any lawfully practising physician, whether regular, homœopathic, eclectic, or what not, a "quack;"¹⁰ a rule in accord with the English decision above referred to, that it is no libel to write of a regular practitioner that he meets homœopathies in consultation. But, nevertheless, it would seem from the cases that a physician of the greatest attainment may be called a "quack" if he be not licensed to practise within the jurisdiction. Thus, in a leading English case,¹¹ defendant, Dr. Carnegie, appears to have said: "I know no such person as Dr. Collins, but I do know such a person, by name Joseph Collins, who calls himself Dr. Collins; but such a person I know to be an impostor and a complete quack, and has not the slightest title to such an honor, as I have made inquiry at the different colleges; Dr. Collins is a quack and impostor." "A man of his description would be guilty of anything; I will do everything in my power to oppose such a character while here." Carnegie also used words imputing drunkenness and malpractice. Collins sued on six counts, and having proved that St. Andrew's University had conferred upon him the degree of Doctor of Medicine, recovered a verdict on two counts; but the court, holding under advisement the question of the effect of this degree,

eventually decided that, inasmuch as a Scotch degree conferred no right to practise medicine in England, a verdict must be entered for defendant on all counts charging slander of plaintiff in his profession. Like conclusions have been arrived at in this country and in Canada. Thus, in Kentucky, recently, defendant said of plaintiff: "Have nothing to do with him. He is on doctor; nothing but a travelling quack; knows nothing about medicine, and but little about anything else." The action was dismissed, and upon plaintiff's appeal the court said: "We think appellant was not legally authorized to practise medicine in this State when the alleged slanderous words were published, and, as a legal sequence, has no cause of action therefor."¹ In an older case in New York, defendant wherein had charged plaintiff, a "cancer doctor," unlicensed to practise medicine in the State, with killing a woman and with malpractice, Chancellor Walworth said: "It is not actionable to charge such a person with ignorance of the healing art, or with having destroyed human life by lawful but misapplied and well-intended efforts to preserve it;" but he also intimated that the case might have been different if the words had charged manslaughter, as by alleging that plaintiff had caused death through reckless use, contrary to law, of poisonous drugs, knowing their properties.² So, too, it resulted in the case of Dr. or Mr. Skirving, in Ontario, who sued one Ross for saying that he, Skirving, "was a quack, charlatan, and the lives of the people were not to be entrusted to such a scoundrel, as he was an unqualified medical practitioner;" and also that his papers were fraudulently obtained. It was proved that plaintiff was duly qualified under the medical act (21 and 22 Vict., chap. 90) to practise medicine in any part of her majesty's dominions. But a subsequent act (31 Vict., chap. 29) allowed colonial legislatures to regulate the registration within their jurisdiction of persons already registered under the medical act. And as it appears that Skirving was not registered under the Ontario statute, it was held that he could not maintain his action.³ As a result of these cases it would seem to follow that the courts hold it no slander to say of the most intelligent medical man, if unlicensed to practise medicine within their jurisdiction, that he is a "quack," "a charlatan," "a person ignorant of the healing art," and even "a scoundrel;" upon the ground that the gist of slander is the injury to one in his profession, and no such injury can result, at least in the eye of the law, where his practice of that profession is itself unlawful.

It would also seem a logical conclusion from these cases that the like disparaging remarks might be safely made of one retired from the active practice of medicine; for if he no longer seeks livelihood by his profession, no harm can result to him from sayings imputing lack of medical ability. And yet in common sense a wrong would be done by such statements, for which, even if the words were, technically considered, not slanderous, some remedy should, and perhaps, would, be found by the courts; especially if special damages were laid. A case illustrating the extent to which courts will at times go in redressing a personal wrong, regardless of its technical name, arose in Massachusetts in recent years. Dr. Morasse was a member of the Roman Catholic parish of Notre Dame. His wife procured a divorce in February, 1886, and in the following May, while his pastor, Father Brochu, was in Europe, the doctor married again before a justice of the peace, an act working his excommunication. Father Brochu, after his return, used these words in a sermon to his flock: "During my absence there was a scandal of marriage by law in this parish, and you

know who the person is. On my return from Europe, when I first heard of it, I thought I would say nothing about it, because I supposed he would not have the sympathies of the people. But I see it is not so, and, on the contrary, this person is gaining the sympathies and favor of the people, and that they are running after this person, and they give him the first places. Why do you run after him so? Not long ago I was invited to a party where that person was, and I refused to go, because I would not meet an excommunicated person. If any of you are sick and want my assistance, you need not send for me if that person is there, because I will not be under the same roof with him." Alleging that these words falsely represented him as unfit for society and the practice of his profession, the doctor brought an action for slander against the priest, and proved that, although prior to the sermon he had earned from \$1,800 to \$2,000 a year, in the week after it was preached he earned nothing, and subsequently earned only about a dollar a day until four months later, when he ceased to practise in Southbridge. As showing malice, plaintiff proved the utterance of these other words in a sermon preached after the action was begun: "An action has been brought against me. I am not the party sued. Everything falls upon the congregation. Be not disturbed. The congregation is worth \$60,000. We shall see if the Church shall destroy the vermin, or the vermin the Church." A verdict for \$1,500 was found for the plaintiff and sustained on appeal. It is obvious that the priest neither imputed lack of professional ability to plaintiff, nor charged him with crime under the laws of Massachusetts. And it is difficult to perceive how, consistently with the definitions and laws, the expressions complained of could be treated as slanderous. But the court seems to have reasoned thus: The words were uttered with intent to work temporal injury and effected their purpose; a tortious act was thus committed, and whether it be called slander or not makes little difference; the jury were entitled to find their verdict; because, (1) if they believed that the words, although not defamatory *per se*, were nevertheless uttered maliciously and unjustifiably to cause and did cause temporal loss, such words are actionable; (2) if they believed that this part of the sermon falsely instructed the parishioners that plaintiff was not fit to be employed professionally, and that such employment of him would be at the risk of losing caste in the Church and its holy offices, then they were entitled to find the words slanderous; and the jury were entitled to find that such imputation was false, if the plaintiff, notwithstanding his ecclesiastical disability, was, in their opinion, a competent and worthy physician. The right of the priest to instruct his flock as to the consequences of civil marriages under such circumstances was admitted. His right to say that he personally would not associate with an excommunicated person can scarcely be denied. It seems clear that court and jury viewed the case as one of temporal, ecclesiastical persecution for conduct permissible and innocent under the laws of the State, and reached their conclusions accordingly.

One result of multiform State legislation is that there is no uniformity of standards in licensing medical men. A physician or surgeon, however eminent, may not, solely by virtue of his license in one jurisdiction, practise his profession in every other. He may be a writer of authority, far surpassing the average practitioner in general skill and knowledge, an admitted expert in special branches, and yet, if the strict rule of the cases cited be applicable, he may be called a "quack" with impunity in any State where he is not licensed. Nay, more, formerly in the State of New York—and it may be so now in some other States—a licensed physician registered in one county could

¹ Hargan 70, Purdy, 93 Kentucky, 424; 20 S. W., 432.

² March 75, Davison, 9 Paige, 580.

³ Skirving 75, Ross, 31 Up. Can. C. P., 423.

not lawfully practise medicine in another county, unless registered therein also. Is it to be supposed that if a physician registered in New York City had been called a "quack" in Brooklyn, he could have had no redress while that statute was in force, unless he had been registered also in Kings County? This seems to be a *reductio ad absurdum*, and yet it is but the ruling of the court in the Canadian case of *Skirving vs. Ross*, which holds, as we have seen, that a person qualified under the imperial medical act to practise medicine in any part of her majesty's dominions, can have no redress for a professional slander uttered of him in a colony with whose registration law he has not complied. Eminent medical men frequently visit other States in advisory capacities, to attend professional gatherings, or as expert witnesses. In the States of their own residences they are qualified to practise their profession. Have they no redress if, elsewhere, their professional reputations are assailed? Of course, every case must be decided under the laws of the jurisdiction, and upon its own facts and circumstances. But if the person maligned be not in fact a pretender, it is reasonable to believe that the courts would, as in the case of *Dr. Morasse* just quoted, seek to give him vindication upon some less technical theory than that of the ancients. Certainly, if such a plaintiff were a medical writer or expert authority, the facts that he was not actively engaged in the practice of his profession, or that he could not lawfully practise medicine within the jurisdiction where the slander was uttered, ought not to afford immunity to his defamer.

It is said that the cause of action for slander is transitory, and, when it has once accrued, the action may be brought in a forum other than that in which the defamation was uttered; and so when, both parties being residents of Jersey City, *Vreeland* spoke there words of *Hull*, slanderous at common law, the latter maintained his action in New York.¹ But *Miss Stout*, of Indiana, was not so successful. She brought an action for slander against one *Wood*, who had spoken words accusing her of fornication, words not actionable at common law, but, at least so the court said, "deriving all their turpitude" from the statute of Indiana. She proved that the words were spoken in Ohio, but failed to prove that they were actionable in that State; wherefore it was held that, although slander be a transitory action, yet, since a cause of action must arise in one jurisdiction before it can pass over into another, it was error to have submitted her case to the jury,² the court remarking that in this case they followed a trackless course. Analogous to this is an English case, arising upon an application for a writ of service out of the jurisdiction. It appeared that one *Marescaux*, a passenger on the *Para*, bound from England to Jamaica, complained to the captain that third officer *Bree* had misconducted himself toward a lady passenger. The matter having been reported to the London office, *Bree* was dismissed. He then sought to bring an action for slander against *Marescaux* in England. The court refused the writ, for the following reasons: (1) If the act done, that is, the utterance of the words, were the basis of the action, then, as it was done beyond the jurisdiction, the action would not lie; (2) if, on the other hand, the special damages, that is, the loss of his place, were the cause of action, then, although that damage occurred within the jurisdiction, nevertheless it resulted from the captain's repetition and not from *Marescaux's* original utterance of the slander; and as a man is only liable in slander for the direct results of his own speech, and not for the effects of its repetition, again the action would not lie. But, had *Marescaux* written the

charge in a letter and sent it to England, thus libelling *Bree*, the case would have been different.³ Whether, then, a physician dubbed a "quack" in a jurisdiction wherein he is unlicensed to practise, can have a remedy, depends largely upon the particular statutes and the peculiar circumstances of each case. In the State of New York, since, at present, a physician from abroad may enter any county for consultation, such an one could maintain an action if so defamed. In other jurisdictions the case might be different. The truth is that our forebears, pugnacious and irascible men, never encouraged the seeking redress in court for transitory exclamations of passion or abuse, considering them as the fruit of impulse rather than of malice, and, perhaps, to be settled rather by the rules of the ring than by those of the forum.

When we come to libel, however, the rule is different; and therefore *Dogberry* cried, although not in *Job's* spirit, "Oh, that I had been writ down an ass;" for if he had been writ down he might have had his action against *Conrad* for libel; whereas, that worthy's exclamation, "You're an ass. You're an ass," was no slander. And in this *Dogberry's* legal position was sound, for, shortly after his time, it was expressly held that it was not slanderous to say of a justice of the peace, "He is a fool, an ass, and a beetle-headed justice," those terms not affecting him in his office, but being only such general abuse as the law winks its eye at, if uttered orally. But the court agreed "That the defendant deserved to be bound to his Good Behaviour for his Sawciness of a Magistrate."⁴

If the Massachusetts court ignored the technicality of the law in order to sustain *Dr. Morasse's* verdict in his action for slander against *Father Brochu*, the Mississippi tribunal availed themselves of extreme technicality to defeat a jury's finding for plaintiff in an action for libel growing out of the political murder of *Miss Chisholm* and her father, in that State, in 1877. The *Vicksburg Herald*, in an article entitled "Rash Southerners and Philanthropic Northerners," mildly deprecating the "unfortunate occurrence," as such episodes used to be called, said: "The accident of *Miss Chisholm's* death, caused by malpractice, and not by her slight wound, adds tenfold to the deplorable consequences." The murdered girl's surgeon brought an action and recovered \$500. But the appellate court set this small verdict aside, (1) because the trial judge's charge "assumed that the word malpractice meant gross ignorance and unskilfulness, which is only one of its ordinary meanings," instead of leaving it for the jury to decide in what sense it was used; (2) because a witness had been allowed to testify to the technical meaning of the word; and (3) because defendant, having introduced evidence of improper treatment without objection, was not allowed after the court's charge to amend his plea, so as to set up justification: a righteous decision, perhaps, but of the sort that makes uninstructed laymen cry, "Woe to them that call evil good and good evil," for it would seem that no amount of theorizing or hair-splitting can alter the fact that, to common sense and understanding, it is so defamatory to attribute a patient's death to the surgeon's malpractice that any other person would hesitate to employ a practitioner so charged. In a comparatively recent New York case,⁴ the evidence went to prove that defendant said among other things, in speaking of an amputation by plaintiff: "It would have been better to have taken off the other arm, then he would have had the right arm to use; it was a perfect piece of malpractice; it was the biggest piece of malpractice he ever knew or heard of."

¹ *Bree vs. Marescaux*, 1, R. Q. B., 7, 434.

² *Bill vs. Neal*, 1 *Leving*, 52.

³ *Rodgers vs. Kline*, 50 *Miss.*, 808.

⁴ *Lynde vs. Johnson*, 39 *Hun.*, 12.

¹ *Hull vs. Vreeland*, 42 *Barb.*, 543.

² *Stout vs. Wood*, 1 *Blackf.*, 71.

He cut the arm off, and got his name up and got a big fee. He acted hastily." No special damage was averred, and a verdict was found for defendant. A motion for a new trial on exceptions alone was denied. The opinion, dealing only with questions of law, is highly technical; but it is of interest here because, although it holds the statements that plaintiff in amputating acted hastily and without sufficient examination, and that he might better have cut off the boy's left arm, etc., were not actionable *per se*, nevertheless it carefully points out that the exceptions do not raise the question whether the words charging "malpractice" were actionable *per se*, and expressly states that the court does not hold that they are not so. From this it seems a fair inference that, if that question had been before the judges, they would have differed with the Mississippi court, and found the charge of malpractice actionable *per se*.

Since any written words holding a person up to scorn and ridicule are libellous, it is not necessary, as in cases of slander, that, in order to be actionable, they should refer to the party defamed in his profession. But let a modern instance serve to show at once how judges, as well as doctors, disagree in their professional diagnosis of a case, and how difficult it is to prophesy what will or will not be considered libel by the courts. The Rochester *Democrat and Chronicle* spun a little romance of the finding of Farmer Hammell, apparently frozen by the wayside, the proceedings before Coroner Purdy, and the resuscitation of the supposed corpse by Dr. Lester. Romance seems to be the proper word, for the general term's opinion states that the publication was "conceded to be false." Among other things, the newspaper said: "To all appearances the man was frozen; the limbs were rigid, the face was pale, the eyes had a glassy look and there was no sign of life. . . . Coroner Purdy arrived, summoned a jury, and began to inquire, according to law, how and by what the man then and there lying dead came to his death. Dr. Lester looked at the supposed remains, and after a careful examination said the man was alive. They laughed at him, but he insisted so strongly that life was still within the stiffened body, that Nicholas Durnir, a brother-in-law of the deceased, caused the body to be removed to his store. The coroner's inquest was then interrupted, and the inquest and perhaps a funeral was averted." The article then describes the resuscitation, and concludes: "Mr. Hammell can thank Dr. Lester for the fact that the coroner's jury did not return a verdict that he came to his death from exposure, that he was not placed in a coffin and buried alive, and that his family and friends were not called upon to mourn his unfortunate death." Now if so happened that Coroner Purdy was also a practising physician and surgeon; and the publication being concededly false, as appears from the opinion of the general term, he brought his action for damages. When the case came to trial, the circuit judge directed a verdict for defendant, on the ground that the publication was not libellous *per se*, and there was no proof of malice. Plaintiff appealed to the general term, who granted him a new trial, saying: "To make the publication libellous *per se*, it was only necessary that it should tend to bring the plaintiff into obloquy or disgrace, ridicule or disrepute. Can it be said that such was not the tendency of the publication in question? Was it not calculated to bring disgrace or ridicule upon a physician to say of him, in substance, that he did not know on inspection whether a man was alive or dead? And was there not the same injurious tendency in the comparison implied in the last statement of the narration, viz., that the man might thank Dr. Lester that he was not pronounced dead and buried alive?"

"It is true that the publication does not mention

the fact that the plaintiff was a physician, but he was so in fact, and was known to be so by the public among whom he lived; and the publication had the same tendency to bring him into disrepute as a physician where he was so known, as if it had named him as such. It is not necessary to mention a man's profession or calling in order to libel him in it."¹

The three judges of general term concurred in this apparently lucid opinion, which has been quoted at such length for purposes of illustration and contrast. In some less fortunate jurisdictions, an appeal having been had and three judges out of four having decided the words to be libellous *per se*, that point would have been deemed settled. But in New York, with its blessed privilege of an appeal from an appeal, there yet remained seven judges to pass upon the question, which, like the farmer himself, was only apparently settled; and so the defendant, worsted below, appealed unto Cæsar, and this is the way in which the matter struck our judges of last resort, who were unanimous in their opinion, as the general term had been in theirs: "We are unable to find in the words used or the general scope of the publication any slanderous or defamatory meaning, nor do we perceive that it is susceptible of any construction which would make the words actionable. It appears from the complaint and evidence that the plaintiff was by profession a physician and by office a coroner. In the article complained of he is referred to in the latter capacity only, and nowhere can be found a word or suggestion from which the most astute inquirer could infer that he had any other than that public occupation. As the language used did not relate to his profession in any way, so as to his office of coroner, it exhibits on his part a prompt and efficient performance of its duties, and it is impossible to see how any person reading it could ascribe to the words used a defamatory meaning, or, without the innuendo, apply them to the plaintiff in his professional capacity, and there is no evidence that such application was intended. . . . The plaintiff was not spoken of as a physician; he was not described as acting as such on the occasion in question, and if we assume, with the plaintiff's attorney—as I cannot, in fact, concede—that the language of the defendant could in any connection be deemed actionable, it is not so here."² The only authorities cited by the court of appeals to support this reasoning are two cases of slander, not of libel. The gist of the general term decision, that the article was libellous, in holding up plaintiff to ridicule, as sitting coroner-wise on a live body, is ignored. Let us suppose that the newspaper had told the story in this way: "Hiram J. Purdy, one of the coroners of Seneca County, is lamentably ignorant of medical science. He is, to be sure, an efficient and zealous coroner. He sits on bodies promptly and well. But, unfortunately, he does not always know whether the body he is sitting on is alive or dead; this is proven by the fact that he held an inquest on the live body of Farmer Hammell, and the latter would have been buried if Dr. Lester had not discovered that the coroner's supposed corpse was alive." There is here no more reference to the fact that the coroner is a physician than there was in the actual publication; the reasoning of the court of appeals is just as applicable to one set of words as to the other. But will any one say that our hypothetical words would not disparage in his profession and make ridiculous to all who knew him any physician of whom they were uttered, even though he happened to be also a coroner? Perhaps the result arrived at by the highest court in this case was correct—the publication may not have made its victim ridiculous among his neighbors. But, if so, he was

¹ Purdy vs. Rochester Printing Co., 26 Hun, 206.

² Purdy vs. Rochester Printing Co., 96 N. Y., 372.

saved from ridicule, not because the article described him as a coroner, but because his alleged failure to recognize life under the circumstances was a mistake that might have been made by any physician of average knowledge and skill; so that, in this particular case, to attribute such error to him, even as a physician, did not necessarily injure his reputation or make him ridiculous, and therefore was not actionable, in the absence of proof of special damage.

If a medical practitioner makes himself a laughing stock by efforts to achieve notoriety, he cannot recover damages from those who further his attempts. Henry Sullings wrote a gratuitous puff of himself for the *Kalamazoo Gazette*, published by his friend, Andrew J. Shakespeare. When the article appeared, thanks to the printer or the devil, he was represented as having skilfully removed a "patty tuber" from the "hypogastrium" of A. B. Smith. Sullings sued Shakespeare for libel, but failed to show that the defendant was responsible for the new medical nomenclature. The plaintiff was not only defeated, but received a sharp admonition from the court, who said: "We cannot forbear, in the interests of public morality, to call attention to the fact that the plaintiff, if a physician, has no right to publish matters of professional confidence, and that the article, if published as he wrote it, without the approbation of the person operated on, would have been a very plain breach of professional duty."¹

And this brings us to consider for a moment defamation by medical men. Not only is it the obvious moral duty of physicians and surgeons to guard sacredly their knowledge of patients acquired in their professional relations, but in almost every State physicians are exempt, or expressly prohibited, from revealing such knowledge, even on the witness stand. To falsely attribute a contagious disease to any one is, as we have seen, a slander. And if a physician should do this unnecessarily or negligently he would be liable in damages, even if his statement were due to mistaken diagnosis. Of course, the case would be different if he were under a duty to disclose the fact. A case illustrative of this point, although not founded on defamation, arose in this city. Dr. Purdy, a physician of standing, formerly president of the medical society of the county, was called to attend a patient, Miss Brown, whose skin was in eruption. The physician, diagnosing the case as small-pox, properly reported his opinion according to law to the health authorities, whose inspectors, upon their own diagnosis, removed Miss Brown to the small-pox hospital. The patient brought an action against her physicians for damages, alleging mistake and lack of skill in diagnosis, and negligence. She won a verdict, but on appeal the judgment was reversed, and she was said to have no cause of action, on the ground that the physicians were not responsible for the acts of the health officers.² But if physicians should falsely report to persons with whom they had no duty to communicate, that the patient had small-pox, an action for slander might be maintained against them, as well as against laymen who should make a like report.

And this suggests the protection of privilege. In the law of defamation, any statement is privileged that A makes to B in good faith upon a topic in which both have such an interest, or in reference to which both have such a duty, whether legal, moral, or social, as to make it proper for A to speak and for B to hear. But the extent of this privilege is no more than this—that the statement covered by it is not actionable, even if false and defamatory, unless proved to have been made out of express malice, or, what is the same thing, with gross negligence; in other words, privi-

lege means that malice is not to be inferred merely from the falsity and defamatory character of a statement, but must be proved. Three New York cases will serve to illustrate the point. One of them¹ has been referred to already. There it was held that a person could not misuse the privilege of a witness to defame a fellow-practitioner by irrelevant criticism of his professional attainments. In another case,² it appeared that one Mr. Fawcett obtained admission to the Allegany County Medical Society upon a diploma of the Royal College of Surgeons of Edinburgh, stating that he was qualified to practise surgery. That document was handed about in the society, but, being in Latin, no one could understand it. Dr. Charles, learning subsequently, from exoteric sources, that the diploma did not authorize the holder to practise physic, introduced a resolution for the expulsion of Fawcett from the society, upon the ground that he had obtained admission to it by false pretences. This resolution having been adopted and published in the *Allegany Republican*, Fawcett brought his action against Charles for libel. The court held that the society had no jurisdiction to act, and that the resolution was, therefore, not privileged. A somewhat similar action is now pending in New York City, growing out of criticism, by a member of the county society while upon the floor, of an advertisement printed in the society's directory. The third case³ showed these facts. Dr. Allan McLane Hamilton, as assistant inspector of the Board of Health of New York City, made, in the line of duty, an official report, published in the *City Record*, recommending a certain kind of pavement. Mr. Amos F. Eno wrote a letter to the *Tribune*, intimating that the motive of the official was open to suspicion. Dr. Hamilton promptly brought his action for libel to vindicate his character, and, Mr. Eno's plea of privilege being unsuccessful, obtained a substantial verdict. The case was taken up, and the court of appeals held that, while the occasion was such as to make the defendant's letter privileged, since the report was before the community and, as to its facts, open to criticism and to attack even by satire and ridicule by any citizen, yet there was no privilege to go beyond criticism of the report and assail the character of the writer. The verdict in Dr. Hamilton's favor was therefore sustained.

Defamation is a personal wrong; so is false imprisonment; and actions growing out of both are analogous. Thus a recent New York action⁴ for the latter cause is relevant to our inquiry. Plaintiff was committed as insane by the recorder of Albany upon the certificates of two physicians. A trial of the issue of insanity resulted in his discharge as sane; whereupon he sued the recorder and the doctors. It was held that the former acted in a judicial capacity upon the facts stated by the physicians, and was not liable, but that the physicians themselves, as experts, possessed no judicial immunity, and owed the duty to plaintiff of exercising ordinary care and skill. The rule would be the same in libel.

It is, of course, easily possible for physicians to defame or be defamed by those who purvey articles of use in medical practice. A surgeon of New York once complained to me that in all cases in which he used ligatures furnished by a certain house, suppuration supervened. This coincidence justified investigation and comment, and if the ligatures were septic, the dealers were liable in actions for negligence; but, if incorrect, the statement was defamatory. And a similar report that the silk of a certain manufacturer contained enough arsenic to hurt the factory hands was

² Brown vs. Purdy, 54 Super. Ct. (22 J. and S.), 109.

held in Massachusetts to be slanderous.¹ A case converse to this arose of late in Louisiana, where the civil law does not recognize the distinction between words actionable *per se* and those requiring proof of special damage. A pharmacist declined to compound two prescriptions written by a certain practitioner—one containing as a component a patent medicine whose ingredients he did not know, and the other calling for articles he did not have. Afterward he spoke words belittling the physician's ability, saying that his diploma was not worth a straw. It was held that his refusal to put up the prescription gave no cause of action, even though it created a presumption of the doctor's lack of professional skill, since the druggist had the right to distrust his own or the physician's ability. But the defamatory words were said to be slanderous.²

I have thus tried to illustrate the application of the law in cases of defamation wherein medical men have been the *dramatis personae*. There would be no such cases if Arthur's charge to his Round Table were observed, "To speak no evil, no, nor listen to it." Unfortunately for parties, fortunately, perhaps, for lawyers, the precept has been and always will be broken by the envious and the irascible.

REPORT OF A CASE OF DISLOCATION OF THE TESTICLE INTO THE PENIS.

By RAMON GUTERAS, M.D.,

NEW YORK.

THE patient, J. C.—aged fifty-two, a piano mover, was referred to me at the Post-Graduate Medical School by Dr. Medina, the surgeon of the Northwestern Dispensary, on account of a deformed condition of the external genitals following an accident.

Previous History.—This shows nothing of interest in relation to his present trouble. He has never had any venereal disease nor any trouble with his genito-urinary organs, excepting a few attacks of urethritis of short duration without complications.

History of his Present Trouble.—This is briefly as follows: About two months ago he was riding on a cart loaded with radiators, which was being towed by a heavy truck, and noticing that a piece of rope had fallen from the truck, he jumped off the front of the cart to pick it up.

On striking the ground he slipped and fell and the wheel of the cart passed up between his legs over his left pubic bone, groin, and flank on to the left side of his thorax when it glanced off.

After the accident he tried to get up but found that he could not support himself on his left leg, which seemed to be limp and powerless. In addition to this he felt a severe pain in the region of his left hip and loin where the wheel had passed over him.

He accordingly lay by the roadside for a while until an ambulance could be summoned, which conveyed him to the nearest hospital. On arriving there he was examined by the house surgeon who found that his sixth and seventh ribs had been fractured in the axillary line, that the region of the left hip was very much contused, and that the wheel had cut through the soft tissues in the left pubic region, lacerating the superficial external pudic, the superficial epigastric, or some other of the small branches of the femoral in that region, from which a profuse hemorrhage had taken place.

The patient was placed upon a water bed and his fractured ribs were duly attended to.

Later in the day his scrotum, penis, and the adjoining region of his left thigh and hip were seen to

be much swollen and bluish-black in color, giving rise to a considerable amount of pain. An ice-bag was therefore put upon his genitals and he was made as comfortable as possible.

At the end of a week the swelling and pain had diminished to such a degree that the ice-bag was discontinued.

The patient remained in bed for about three weeks, during which time the principal pain seemed to be in his hip, although his penis felt sore and sensitive.

During his stay in the hospital he felt quite comfortable while lying quietly on his back, but immediately on raising himself to a sitting posture he noticed a feeling of faintness accompanied by nausea and dizziness. On leaving the hospital at the end of three weeks he still felt weak and was obliged to support himself on two pieces of fence railing. On reaching his home he again went to bed and remained on his back for nearly two weeks longer. Shortly after this he consulted Dr. Medina who referred him to me for treatment.

Observations at the Time of the Examination, that is, on presenting himself at the Post-Graduate Medical School. The patient was a large, powerfully built man, as one would expect to see in one of his vocation. His general condition seemed to be good and he said that he felt well with the exception of some pain in his hip and a feeling of pain and discomfort in his

FIG. 1.

penis, which was especially marked when moving about.

On questioning him in regard to the condition of the functions of his genito-urinary organs he replied that he had had no difficulty in urinating since his injury, but that he had had no erections since that time, although he had considered himself well preserved and vigorous before the accident.

Examination locally revealed a scrotum which

¹ Elmer vs. Fessenden, 151 Mass., 359.

² Tarlton vs. Lagarde, 46 La. Ann., 1368.

looked flat and empty in its lower portion, while in the upper part of the sac a nodular mass was present. Over the upper and anterior surface of the scrotum a small wound was noticed which had not as yet entirely healed. This was the one caused by the passage of the wheel over this region, from which the hemorrhage

FIG. 2.

already alluded to had taken place. The penis looked flattened and abnormally wide at its base, where it measured five and a half inches in circumference and two inches in width. The left side of the organ appeared to be especially bulging from behind the glans to the pubes and on palpation had the peculiar elastic feel resembling that known as testicular. On more careful manipulation it was observed to be oval in shape and directly connected with the nodular mass at the peno-scrotal junction on the left side (see Fig. 1).

On elevating the penis to obtain a view of its under surface the deformity was much more marked and the relation between the mass in the left side of the penis and that in the scrotum was more clearly discernible (see Fig. 2).

Palpation of the scrotum below the nodular mass revealed an elongated body extending from it down to nearly the bottom of the scrotal pouch where it was felt to be again slightly expanded.

The case was evidently one of dislocation of the testicle into the penis and the points of interest were, first, how it had been accomplished and, second, how to reduce it. In order to decide upon the first point, namely, how it had been accomplished, it might be well to consider briefly the anatomy of the parts in question and their relations.

The testicle as we know is an oval gland, upon the outer edge of the posterior border of which is a long flattened body, the epididymis. This consists of an upper expanded extremity, the globus major, which is

intimately connected with the upper part of the testicle by its efferent ducts; a central portion or body; and a lower extremity also slightly expanded, the globus minor, which extends into and is continuous with the cord. The tunica vaginalis is the serous membrane covering the testicle and epididymis and lining the scrotum. It is derived from the peritoneum during the descent of the testicle. It has a visceral and a parietal layer; the former covers the testis and the epididymis and connects the two by a distinct fold; the latter lines the wall of the inner surface of the scrotum. The scrotum which contains the testicle and epididymis and is lined by the tunica vaginalis consists of an integument which is continuous with the skin sheath of the penis, and a dartos or its proper tunic which is continuous with the dartos sheath of the penis.

As in this patient the oval body in the left side of the penis seemed to be the testicle, the nodular mass in the upper part of the scrotum the globus major, and the elongated mass extending from the nodular portion in the upper part of the scrotum nearly to the bottom of the pouch the body of the epididymis and the globus minor, it was evident that the testis had been torn away from the body of the epididymis and the globus minor, had been turned upon the globus major, and then been forced through the parietal layer of the tunica vaginalis and beneath the dartos sheath of the penis.

This conclusion of the manner and variety of the dislocation having been arrived at, the next or second point for consideration was how to reduce it.

As it had been for so long a time displaced and was evidently bound down by adhesions, it did not seem probable that it could be reduced excepting under an anæsthetic and probably not even then without resorting to operative interference; I therefore referred him to the Columbus Hospital for further treatment. On the following day the patient was etherized by the Carter Cole method, that is, by mixing oxygen with ether in the ether-can, and reduction was attempted by external manipulation without success. Accordingly an incision was made over the lateral aspect of the penis corresponding to about the centre of the mass from about an inch behind the glans to the peno-scrotal junction on the left side. The integument and the dartos sheath having been cut through, the testicle was brought into view lying beneath. An attempt was then made to push the testicle down into place, but the adhesions were found to be so strong that this could not be accomplished. Accordingly a second incision was made from the peno-scrotal junction on the left side down over the part of the scrotum covering the globus major of the epididymis, and the adhesions which were principally about the globus major and that part of the testicle adjoining it were broken down. This same incision opened the upper part of the pouch of the tunica vaginalis, so that after the testis had been drawn out of its place of confinement an attempt was made to push it once more into its former abode. The sac, however, seemed to be too small to contain it, due probably either to inflammatory changes or to having shrunk owing to the absence of the gland during this short period. It was necessary therefore to stretch it with the fingers before the testis could be made to enter.

After the testis had been replaced and the contents of the scrotum were once more in normal relation to one another, they were carefully washed with a warm solution of boric acid and their coverings once more put back into place.

The dartos sheath of the penis was united with a continuous catgut suture and the skin sheath with silk, while in the scrotum the tunica vaginalis was united with a continuous Lembert suture of catgut, and the

integument and dartos with silk. The dressings were of the usual order.

The patient stated that he had an immediate feeling of relief on coming out of the ether after the operation. Three days later some of the stitches were removed, and at the end of six days the remainder were taken out. The patient was then able to stand erect and walk about with comparative ease. The soreness in his penis had disappeared and with the exception of a slight pain in his hip he felt entirely well.

One month later the patient called at the office and stated that his genital organs were in the same condition as before the accident, with the exception of a slight amount of tension noticed on the injured side of his penis when in a state of erection, due probably to the cicatrix left after the operation. He also stated that he had had intercourse and the accompanying ejaculations were without pain. His hip, however, was still weak.

23 WEST FIFTY-THIRD STREET, NEW YORK CITY.

NOTES ON URINE ANALYSIS.¹

By E. E. SMITH, Ph.D.,

PHYSIOLOGICAL CHEMIST.

I. Tests for Traces of Albumin.—The writer has so frequently been asked to recommend qualitative tests for traces of albumin in urine that he is led to give the following description of the methods he employs:

The first essential for a delicate albumin test is to have the sample of urine perfectly clear. To those who are satisfied to test turbid urine, even though the turbidity be slight, these notes can be of no service, for they are of value only in testing clear specimens. If the urine is acid and fresh it is usually rendered perfectly clear by filtration, filtering through a wet plaited filter paper several times, if necessary. If the reaction is amphoteric or alkaline, the previous addition of one or two drops of dilute acetic acid may be of advantage. Specimens that cannot be clarified in this way are made alkaline with a few drops of solution of caustic soda and then filtered. The separated phosphates serve to carry down bacterial debris and to fill the pores of the filter-paper, sufficing in nearly every instance to clarify the specimen. Occasionally, however, a decomposed specimen is not entirely clear even after this treatment, in which case the precipitate of phosphates may be increased in bulk by the addition of ammoniacal magnesium mixture. The addition of dry solids to the urine for the purpose of clarifying is not to be recommended. This procedure, while perhaps it may not always remove mere traces of albumin, is certainly liable to remove a considerable portion, if any quantity is present, and hence can only be used, even by a competent chemist, with extreme caution.

The first test is the nitric-acid contact test. About a half-inch of pure concentrated nitric acid is placed in a test-tube, and an equal or larger amount of urine allowed to flow gently on to the surface from a pipette. With care this can be done so as to avoid any mixing of the two fluids. Concentrated or dark-colored urines are diluted with an equal volume of water before testing. In the presence of any but a mere trace there is a separation of albumin at the contact zone forming the so-called albumin ring. A cloudiness appearing above the contact zone is not indicative of albumin, but in nearly every instance, if not always, is due either to nucleo-albumin, which is the albuminoid basis of bladder mucus, and which has been called, though erroneously, mucin, or to the separation of

urates. A diffused haze does not signify albumin. This test is significant of albumin only when there is a distinct and clearly formed white ring at the contact zone.

I have described the Heller test first, because it is the least delicate of the tests I shall describe, though, when positive, it is the most satisfactory; and further, it is the test which I am accustomed to employ first when examining a specimen. If it is positive and is verified by the heat and nitric acid and the ferrocyanide tests, the presence of albumin is satisfactorily demonstrated. At the present time I particularly desire to speak of methods of detecting albumin where Heller's test is doubtful or negative. It is then that it requires especial care and caution to determine the presence or absence of traces of albumin. Such traces may usually be of no significance, yet in some clinical conditions they perhaps are, and at all events the question is frequently presented to the analyst and must be correctly answered.

The two remaining tests I shall describe are the heat and nitric acid and the ferrocyanide tests.

About an inch of the clear urine in a test-tube is heated to boiling, after which two or three drops of ten-per-cent. nitric acid is added. If after a few moments there is no reaction for albumin, the contents of the tube are again boiled and about ten drops of the nitric acid further added, and the tube set aside.

A quarter of an inch of a clear five-per-cent. solution of potassium ferrocyanide is placed in a test-tube, an equal volume of dilute acetic acid is added, and the whole poured into an inch of clear urine in another test-tube, the liquids being well mixed by pouring from one tube to the other several times. The test tube is then set aside. A comparison tube is prepared as follows: An inch of the urine, clarified at the same time as that previously used, is placed in a test-tube and two drops of dilute acetic acid are added. This tube is likewise set aside.

In forming a judgment regarding the presence or absence of mere traces of albumin there are several points to bear in mind. In the literature of urine analysis there is continual reference to the presence of mucin in the urine. More careful study of bladder mucus has, in late years, shown that bladder mucus does not contain mucin but a proteid at least resembling and probably identical with nucleo-albumin. Now the older method recommended for removing mucus, that is, the addition of a few drops of acetic acid to the urine before filtration, worked admirably in removing the saliva mucin which had been added to the urine for the trial tests, but unfortunately with urine containing true mucus, where nucleo-albumin and not mucin is the albuminoid basis, this procedure is not so satisfactory, for nucleo-albumin is only incompletely precipitated by acetic acid. Bearing this in mind, the following interpretation of the heat and the ferrocyanide tests will be understood. If both react positively either a trace of true albumin or of mucus is present, to decide which it is necessary to observe the comparison tube, in which, if mucus is present, there will be some turbidity from the partial separation of nucleo-albumin. If the urine in the comparison tube remains perfectly clear and the reactions with heat and with ferrocyanide present the appearance characteristic of the albumin tests, then it is safe to conclude that a mere trace of true albumin is present, but the appearance of even a slight cloudiness in the comparison tube is to be taken as evidence of the presence of mucus, to which then the delicate heat and the ferrocyanide tests are to be attributed. Since the separation of nucleo-albumin in the comparison tube is only partial, it is evident that no comparison can be made between the intensity of this reaction and the heat and the ferrocyanide reactions.

¹ Read before the Section on General Medicine of the New York Academy of Medicine on December 17, 1895.

The appearance characteristic of the heat and nitric-acid reaction with a trace of albumin is either the formation of a few flakes of coagulated albumin or the formation of a general turbidity which finally results in a fine flocculent separation, persisting when the solution is hot. The addition of one-third to one-half the volume of alcohol causes the flocculent appearance to become more pronounced, while any separated resinous substances, thymol, etc., pass into solution.

When traces of true albumin are present, the ferrocyanide test gives a finely flocculent appearance, while with nucleo-albumin a mere opacity is more common.

Finally, it is to be remembered that albumin is to be considered absent from a urine till its presence is demonstrated by methods which admit of its distinction from mucus. Undoubtedly the safest basis for interpretation, except perhaps in the hands of the skilled analyst, is the requirement of all three reactions here described, ignoring entirely the presence of such mere traces as fail to respond to the Heller test.

II. Standards in Quantitative Urine Analysis.—In the interpretation of the analysis of a twenty-four-hours' specimen of urine, the wide limits of variation in health must be recognized. By far the most important factor influencing the composition of urine is alimentation. Other factors, in health, are relatively unimportant. If, then, some way exists of checking this varying factor a constant or limit of variation can be obtained for each urinary constituent, which will serve for a basis of comparison for pathological urines. Evidently the most direct procedure is to obtain the exact analytical data of all food ingested. Then it is seen that the urea varies with the amount of nitrogenous food, that phosphates and total sulphates likewise vary directly with the proteids ingested, as does also the uric acid and even the ethereal sulphates. In other words, that the amount of nitrogenous food is, in health, the factor producing any considerable variation in the amounts of the important urinary constituents. Unfortunately, it is rarely possible to obtain the analytical data of the ingesta and never practicable, so that we are forced to an indirect method of obtaining urinary standards, a method, necessarily, which is applicable as well in practice. It is known that the amount of urea, or more exactly the total nitrogen of the urine, is dependent upon the amount of proteid, rising and falling in proportion to the amount of nitrogenous food ingested. A method, then, of indirectly estimating the amount of proteid food absorbed, consists in estimating the total nitrogen of the urine; and since proteids alone contribute to any considerable extent to the composition of urine, the total nitrogen becomes the standard of comparison for the other constituents. That the results may be more intelligible I have been accustomed to express the total nitrogen as urea, though this has some disadvantages in research work but less so in practice. Thus, in health, the uric-acid ratio varies, as you know, from 45 to 60, the total phosphate ratio (P_2O_5) between 12 and 15, the total sulphate ratio (H_2SO_4) from 10 to 15, the numbers representing in each instance the quotient obtained by dividing the amount of urea by the amount of the particular constituent. Instead of studying the relation of the urea and ethereal sulphates directly it is customary to compute the ratio of the preformed and ethereal sulphates, which procedure, it is readily seen, is only an indirect way of doing the same thing.

My reason for inviting your attention to the interpretation of results in quantitative urine analysis is because of the occasional objection that I notice in the literature to the method which I have described, an objection coming in some instances from promi-

nent investigators in this subject. Thus Salkowski early raised the following objections:

1. No definite number can be adopted for expressing the ratio of uric acid to urea, since the relation is influenced by the amount of urea excreted.

2. In investigating the influence of any substance upon the amount of uric acid excreted, it is only possible to draw a definite conclusion from the relation of the uric acid and the urea when the urea excreted is the same or nearly the same both in the normal period and in the period of experiment.

Hence Salkowski concludes that the study of the ratio is to be abandoned altogether and the absolute amount of uric acid excreted adopted as the basis for interpretation, an opinion in which Kuehnau recently concurred in his article "Experimental and Clinical Investigations on the Relation of Uric-Acid Separation and Leucocytosis."¹

The objection that no definite number can be adopted for expressing the urea to uric-acid ratio is to some extent correct. Thus Haig's statement that the formation of uric-acid is always in relation to the urea formed of 1 to 33 is entirely disproved by the observation that the relation normally varies at different periods of the day.

It is a fact, however, that the relation of the uric acid and urea of a twenty-four hours' excretion is fairly constant, in health, and that the limits of variation are more or less definite, particularly in the same individual. While then no definite number can be adopted, as Salkowski states, a definite limit to the uric-acid ratio in health can be fixed as Herter and Smith² have shown. Further, in disorders of nutrition there is an increase in uric acid and these limits of health are exceeded, the relation becoming, therefore, a practical index in diagnosis. It is, of course, to be recognized that other factors may give rise to increased cell destruction and consequent increased uric-acid excretion, but when by studying the ratio we have eliminated the major factor and by repeated observation have obtained the limit of variation of the ratio in health, we have a convenient and safe basis for interpretation in disease.

Salkowski's second claim, that in investigating the influence of any substance upon uric-acid excretion the urea eliminated must vary within narrow limits, if the ratio is to be the index of uric-acid excretion, is also in some instances correct. Thus a variation from 55 to 50 might be produced by varying alimentation, independent of the substance administered, and, to go further than Salkowski, might be produced by varying alimentation even if the urea eliminated were constant, so that in such a case the ratio would be misleading even if the urea were identical in the normal and experimental periods. To make this clearer, even though the urea were constant it might result from a different dietary, and the change in diet and not the substance administered might be responsible for such a slight variation in uric-acid excretion as would change the ratio from 55 to 50. In this case it would be necessary, then, to have the urea the same in both periods and the result, as well of the same conditions of alimentation, as for example the administration of the same form of food. But suppose in studying the ratio in health we have, on administering some drug, a variation from 50 to 38 without the intervention of any other unusual disturbing factor, we then know that there is an increased excretion of uric acid without considering the amount of urea, because 38 exceeds the ratio limit under the ordinary conditions of health. In this instance, then, Salkowski's second claim does not hold.

The conclusion, then, seems warranted that slight

¹ Zeit. f. klin. Med., vol. xxviii., p. 546.

² N. Y. Med. Jour., June 4, 1892.

variations in the amount of uric acid, that is, within the ratio limits of health, can be attributed to a particular cause, as, for example, to the administration of a drug, only when all other factors that influence the amount are constant; which means that the subject must be in nitrogenous equilibrium under identical conditions, both in the normal and experimental periods. Under such circumstances it is unimportant whether the interpretation is based upon the ratio or upon the absolute amount of uric acid, since the ultimate result is the same. Where, however, in practice we consider variations that exceed the limits of health, and especially in that class of cases where there is no definite knowledge of the ingesta, Sal-kowski's recommendation that we consider the absolute amount of uric acid may be misleading, and in such cases it becomes necessary to consider the relation of the uric acid to the urea. These statements are illustrated by the following figures quoted from Herter and Smith: '

The twenty-four hours' specimen of a person in health gave:

Urea 38.82 }
Uric acid 0.738 } Ratio, 1 : 54.

A neurasthenic case gave:

Urea.....23.999 } Ratio, 1 : 37.6,
Uric acid...0.637 }

the figures in the latter case indicating an excess even though the absolute amount of uric acid excreted was less than is seen in case 1, which was normal. The value of studying the uric-acid ratio is further brought out by the following illustrations:

Levison, in his work "Uric Acid Diathesis," makes the following statements: "Bodily exercise increases the excretion of uric acid. After rather active muscular exercise in the saddle my excretion of uric acid was on each occasion considerably increased. Two experiments were made, eight days elapsing between them, and the excretion rose by this means, from about 0.6 gramme to 0.981 to 0.985 gramme, and in the second experiment to 1.089 grammes." These figures of Levison certainly show an increase in uric acid. To what extent, though, did bodily exercise increase uric-acid excretion, and to what extent was the increase due to the larger amount of nitrogenous food eaten, which the author himself admits has a decided influence upon the formation of uric acid? Evidently in this case it is quite as probable, so far as any proof is offered, that bodily exercise stimulated the appetite and that the large amount of food increased the uric-acid excretion, as that bodily exercise had any specific influence upon uric-acid formation. Take, on the other hand, an experiment where the uric-acid ratio was used on which to base the interpretation.² Whiskey and champagne were administered to a young man with results as follows:

SHOWING INFLUENCE OF WHISKEY UPON URIC-ACID
EXCRETION.

EXCRETION.		Relation of Uric Acid to Urea.
First day before experiment, no alcohol.....	{ Urea, 31.555 Uric acid, .599	grm. " } 1: 52.6

Relation of Uric Acid to Urea.

First day after experiment, no	Urea,	34.768	grm.	} 1:52.9
alcohol.	Uric acid,	.657	"	
Second day after experiment,	Urea,	32.768	"	} 1:50.1
no alcohol.	Uric acid,	.643	"	

SHOWING INFLUENCE OF CHAMPAGNE ON URIC-ACID
EXCRETION.

			Ratio of Uric Acid to Urea,
First day, 8 oz. champagne...	{ Urea, 31.699	gm.	{ 1:42
	{ Uric acid, .754	"	{
Second day, 16 oz. champagne,	{ Urea, 29.758	"	{ 1:45.1
	{ Uric acid, .655	"	{
Third day, 24 oz. champagne,	{ Urea, 32.172	"	{ 1:46.8
	{ Uric acid, .686	"	{
Fourth day, no alcohol, ...	{ Urea, 32.847	"	{ 1:51.2
	{ Uric acid, .643	"	{

During the time of these experiments the subject was receiving his usual diet and in every way adhered to his customary mode of living, except as stated in the tables. The positive manner in which the increase in uric acid resulting from the champagne is indicated by the ratio, and to what considerable extent the variation in diet is eliminated, are sufficiently evident on examination of the figures.

What has been said regarding the uric-acid ratio may be extended to the phosphates and to all sulphates as well, since these result to such a very considerable extent from the oxidation of the sulphur and phosphorus of proteids.

To what extent the retention of urinary constituents and especially urea interferes with this mode of interpretation I am not fully prepared to say, though it does not seem to exercise any regular or marked influence. Thus the diminution of phosphates in a typical case of interstitial nephritis is well illustrated by the following analysis:

Urea 23.713
Total phosphates (P_2O_5) 0.941 } Ratio, 1 : 25.2

I select at random the following analysis of a twenty-four hours' specimen of urine of a well-nourished man to illustrate how completely the results in health accord with the standards for the method of interpretation described:

		Ratios.
Urea	32.304 grm.	1 : 48.5
Uric acid.	0.662 "	
Total phosphates (P_2O_5)	2.480 "	1 : 13.0
Total sulphates (H_2SO_4)	2.724 "	1 : 11.9

The Twelfth International Medical Congress.—

The date fixed for the next International Medical Congress is the week beginning August 10th, and ending August 26 (new style), 1897. The official announcement will very shortly be sent to the English press. The Emperor has given his imperial sanction to the Congress, and the Grand Duke Sergi Alexandrovitch, the governor of Moscow (and grandson-in-law to Queen Victoria), has granted it his patronage. The nominal president will probably be the minister of public education; the acting president will almost certainly be Professor Klein, the Dean of the Faculty of Medicine in the University of Moscow. Professor Erisman, who holds the chair of hygiene, has, as already stated, been elected general secretary. The meetings of the Congress will be held in the theatres and laboratories of the University Clinique, the so-called *klinitcheski gorodok*, or clinical townlet. Papers and discussions must be in either the French or German language; Russian has been excluded lest the Congress should become national rather than international, and English on the grounds that it is a language little used or understood by other than Englishmen.—*Lancet*.

Clinical Department.

SUCCESSFUL TRANSPLANTATION OF TEETH AND CHLOROFORM ANÆSTHESIA DURING SLEEP.

By E. S. PETTYJOHN, M.D.,

ALMA, MICH.

My little daughter, aged two years and nine months, fell headlong down the cellar-stairs, and struck the two upper middle incisors on the edge of the step, extracting them as completely as if by forceps. The alveolar processes of the right tooth were fractured and the gum lacerated the entire length of the root. After the fright and the crying, which continued a half-hour or more, the child was rocked to sleep in her mother's arms, and placed in her buggy. We found the teeth on the cellar-steps, uninjured. They were placed in a normal saline solution of tepid temperature. On the arrival of an assistant with chloroform for anæsthesia, the child was sleeping quietly. Chloroform was administered without the child awakening, and the teeth were placed within their sockets and pressed into position, the edge of each tooth fitting firmly in a groove of one blade of a pair of forceps, the hand of the operator being placed on the back of the head, with the pressure properly directed. The gums about were cleansed antiseptically, and the teeth left in position without further dressing or application.

The accident occurred about two o'clock, and when the child awoke from her sleep at half-past five, her teeth were in place. The teeth had been out of the mouth fully one hour. Milk and soft food were administered and the lacerated edges of the gums cleansed after eating. Healing of the gums occurred by first intention.

It is now over four weeks since the teeth were placed and they are now solid, in good position, and of normal color. The gums are normal in color and consistency, and the appearance of the mouth quite natural.

I report this as a successful case of transplantation of teeth that had been out of the mouth over an hour, and as another demonstration of chloroform anæsthesia during natural sleep.

ANGIONEURÖTIC OEDEMA TREATED BY PILOCARPINE.

By CHAS. E. NAMMACK, M.D.,

NEW YORK.

MR. M—, thirty-five years old, came to my office, July 5, 1895, and stated that for five years he had been much annoyed, and at times incapacitated for business, by attacks of urticaria, which had resisted all treatment and had recurred in spite of the most carefully followed diet, and a course of treatment at Carlsbad. Remembering the favorable results reported from the use of pilocarpine, I injected, hypodermatically, pilocarpine in gradually increasing doses up to one-half grain. The larger doses acted like a charm on the eruption, and the sialogogue action of the drug would have been promptly manifested, but the patient could not be made to perspire, even when the injection would be followed by active exercise in the sun during midsummer. In order to test the remedy thoroughly, I removed all dietetic restrictions, and the patient kept up the action of the medicine by taking $\frac{1}{16}$ -grain tablets every four hours. On October 3d, he celebrated his immunity from attacks by dining on sauerkraut, German sausages, and Rhine wine, and this remarkable gastronomic conglomeration brought

on a severe attack, which lasted forty-eight hours. A resumption of the pilocarpine again held the attacks in check, such repetitions as occurred being mild in character, localized in distribution, and evanescent in duration. It has been impossible, however, to bring out the sweating effect of the drug, and, following the suggestion of Lustgarten,¹ it is now proposed to administer thyroid extract.

The etiology in this particular case is clearly overwork. About the time of the development of the affection, the man started in business on his own account, and by great energy he has succeeded beyond his expectations. He has no evidence of any neuropathic taint. Direct heredity is wanting. He has never used tobacco or alcohol to excess, and, although he lives in Westchester County, has never had a well-defined malarial paroxysm. There is no periodicity in the time of appearance of the swellings. The closest search has not revealed an attributable cause.

The symptomatology is characterized by the appearance of circumscribed swellings on different parts of the body, by preference the face, throat, and extremities, without apparent cause or premonition, and non-inflammatory in nature.²

He has had thus far no involvement of the mucous membrane of the larynx. There is no heart murmur, no tachycardia, and the urine has been repeatedly examined with negative result. The characteristic features of exophthalmic goitre are wanting.

The pathological character of the disease is the same as that of urticaria, viz., a vasomotor neurosis. In fact, the disease is clinically the giant urticaria of the dermatologists. The pathology explains the beneficial influence of pilocarpine in relieving the attacks by relaxing the spasm of the vessels upon which the resulting exudation depends.

29 EAST TWENTY-FOURTH STREET.

A Word for Alcohol.—"Matthew Arnold had a poor opinion of Carlyle because the Chellean sage preached diligence to a nation already far too zealous in the pursuit of utilitarian as opposed to ornamental things. It cannot be denied that this is the age of restlessness, of over-exertion, and worry, or, as our Gallic friends call it, *surmenage*. Competition, born of love of luxury and fostered by over-population, is so severe that even sluggards are induced to do violence to their natural inclinations by hard work, while people with an aptitude for toil are irresistibly driven to excess. These *obiter dicta* are *à propos* or not, as the case may be, of teetotalism. One favorite argument with total abstainers, based upon the experiments of Kraepelin and others, is the inhibitory action of alcohol upon the brain. A recent writer sums up the question in the following: 'I have quoted enough to prove that even in small doses alcohol does not stimulate but retards vital processes.' Now this is precisely what the too-zealous worker requires. Alcohol prevents the human machine from wearing out prematurely. The neurasthenic brain-user takes his customary dose in the shape of wine, spirits, or more humble beer, and forthwith finds himself, *volens nolens*, incapacitated from continuing his labors. He is compelled to allow his weary brain the rest which otherwise he would deny; alcohol, the fiend alcohol, becomes his guardian angel, saving him from cerebral exhaustion, if not from softening and utter demoralization." But Mr. Smith thinks differently.—*Cor. Lancet*.

Money in it to Him.—"I hear your husband enjoys poor health." "Yes. He's a doctor, you know."

WANDERING KIDNEYS, MOVABLE AND FLOATING.

WANDERING kidneys have probably existed since the fall of man, yet their recognition is an affair of recent date. Fewer than fifteen hundred cases have been reported. Any well-defined constitutional condition, as gout, rheumatism, malaria, can easily mask the symptoms of this particular anomaly. A preconceived idea precludes even the search for it. Hence much unrelieved suffering and impaired usefulness. Do wandering kidneys always produce symptoms and cause distress? By no means; they are often discovered quite by accident, and are of no more moment than certain benign tumors, asymmetries, irregularities in pigmentation, or deviation of the nose to right or left. Disturbances may vary from none at all to those that endanger life, and they bear no necessary relation to the amount of displacement. Widely divergent opinions exist, therefore, as to their power for evil. They are sometimes a source of harm, sometimes not. It requires an open mind, enlightened experience, and a sufficient quantity of sweet reasonableness to decide this question.

The normal kidney has a limited range of movement. When it transcends this, it is said to wander. Wandering kidneys are of two kinds, movable and floating. There are at least fifty that are movable to one that is floating. Sometimes both anomalies exist in the same person. By many, the floating kidney is believed to be nearly always congenital. It may or may not give rise to symptoms. The movable kidney, on the contrary, is more often extremely painful and a source of great irritation. Pressure and traction upon neighboring structures may set up inflammatory action that leads to the formation of adhesions, and thus transform the offending organ into a fixed displaced kidney. Wandering kidneys may be mistaken for tumors of the spleen, liver, omentum, and ovary. They are probably the great originals of so-called phantom tumors—here to-day, and gone to-morrow. Causes are various: traumatism, loss of perirenal fat, childbirth and its accidents, alterations in intra-abdominal pressure, mal-assimilation and imperfect development, and congenital defects of the peritoneum. The condition may appear suddenly, though the majority of cases require months, or even years, for their full development. It occurs most frequently between the ages of twenty and twenty-five; some say between thirty and

forty; and is, for definite physiological and pathological reasons, more common in women than in men. But in men "it is far more frequent than was earlier believed, causing the same general symptoms as in women, requiring similar treatment, and is equally capable of producing disablement and distress. Children are not exempt, and infants are sometimes similarly afflicted. The right kidney is oftener displaced than the left.

The chief symptoms, when any exist, in the earlier stages are digestive disturbances, general nervousness, epigastric pain to the left of the median line, cardiac palpitation, and inability to feel comfortable or to sleep when lying on the left side. These annoyances are more or less chronic in character. Later, pain is a prominent symptom, due to chronic localized peritonitis or to pure neuralgia. Anorexia, nausea, sometimes vomiting, vertigo, anemia, menstrual disturbances, occasionally renal or uterine hemorrhages, despondency, sometimes icterus, and attacks like renal or biliary colic, are now characteristic manifestations.

Careful search should always be made for wandering kidney in conditions in which vomiting constitutes crises. Otherwise serious errors in diagnosis may creep in, for such crises suggest tabes dorsalis, pregnancy, intestinal obstruction, hysteria, uncomplicated neurasthenia, and poisoning. In the sudden attacks of colic, the intense pain is referred to the epigastrium or to the umbilical region, and to the left of the median line. There is a slow, feeble pulse, much prostration, and the face is bathed in sweat. Just previous to and during an acute attack, the urine is diminished. There may be frequent urination, vesical tenesmus, vomiting, and severe diarrhoea. The attacks come on occasionally, then increase in frequency and severity. Complete rest in bed is essential, with gastric sedatives, as chlorhydrate of cocaine; and exclusive milk diet in the beginning, to be followed by eggs, and roast or boiled meats later. Vomiting may occur without pain or neurotic symptoms. It is then most misleading.

There are very few instances of wandering kidney in the female without some abnormal pelvic conditions. Displacements, oöphoritis, salpingitis, inter-menstrual uterine hemorrhage, and prolonged and profuse menstruation, are some of the abnormalities directly due to its influence. No doubt numerous normal ovaries have been removed to relieve grave or moderately severe local and general symptoms, really due to displaced kidney. Pelvic symptoms arise from the intimate relations of renal and ovarian nerves, and from compression of the renal nerves and blood-vessels. In some cases even the vena cava may be compressed.

The ordinary pain (not the acute attacks, resembling renal colic) is at times so severe as to suggest to the experienced the beginning of the first stage of labor. There is similar restlessness, an overwrought condition of mind, similar discomfort and distress, with about the same feeling of general rebellion. No doubt the cause is practically identical: a neuralgia of the lumbo-abdominal nerves. Circulation is much depressed, the appetite is *nil*, urination is frequent and difficult, no position gives real relief, and productive

activity is impossible. Lying quietly in bed is the only resource, with symptomatic remedies.

Through the severity of the pain, the inability to work continuously, the gastric and mental complications, and the alteration in nutrition that these bring about, life may be materially shortened. The dragging pain predisposes to what the French call "a strange melancholy." Lucas has reported cases in which melancholia and mania occurred. The nervous symptoms are perhaps those most likely to be misconstrued. Sometimes they are set down unfairly to hysteria and hypochondriasis. Men and women with an offending, misplaced kidney know that there is something the matter, though often quite ignorant of the real condition. The mental state may be best described as irritation rather than irritability; despondency over limitations rather than complaint of others; exaggeration of unpleasant subjects; and outbursts of sudden anger, with quick remorse and sincere repentance. It is sufficiently characteristic of nervous exhaustion. Chagrin and melancholy at being unable to work, pain, and digestive disturbances have occasionally terminated in death from exhaustion, with no lesion post mortem other than wandering kidney. Keppler has recorded such cases. They are significant and instructive. The patient with wandering kidney is a perpetual object lesson to the neurologist and the gynecologist, and sometimes a reproach to both.

What are the dangers when symptoms are produced? Hydro- or pyelo-nephrosis constantly; general peritonitis occasionally; and destruction of the secretory apparatus eventually. It must ever be remembered that misplaced organs have a tendency to take on disease, and sometimes malignant disease. Interstitial nephritis is a favorite form of degeneration in wandering kidney. Intercurrent disease may also end the many discomforts that have been described. The cause that gives rise to them all does not cure itself, and urgently demands definite and immediate treatment.

What can give relief? Three things—rest, a bandage, and an operation. Rest for a movable or floating kidney that makes itself felt, means a life of partial imprisonment; no great muscular activity, no riding, climbing, no jolting over rough roads, the alluring bicycle nevermore, no rowing, swimming, or even housework that causes any strain. Occupations requiring the upright position are simply impossible. Rest is, therefore, a measure best suited to an income of \$30,000 a year. Various mechanical appliances are recommended. To be effective a bandage must support all the abdominal viscera, and through them the displaced kidney. Elastic webbing entirely encircling the whole abdomen and making as much compression as can be borne, sometimes affords considerable relief. A well-fitting and rather tight corset is of benefit, to men especially, and to women when no uterine trouble exists. External supports contain always the element of suggestion, like mineral waters for gout. But they are a poor second best, since a wandering kidney escapes like quicksilver from the compressing hand, probably the most perfect pad ever known. In the choice of remedial agents, the last

shall ever be first—the operation. Nephrorrhaphy effects a permanent and complete cure in more than half of all cases operated upon. It may be a success surgically in others; and yet the symptoms still remain. Now and then kidneys escape a second time and make excursions as before. This has happened in thirteen cases out of eighty noted by Sulzer. Occasionally the patient dies. As Osler cautiously remarks, the operation does not always succeed. Yet it is the only success possible. The chances are that everything will turn out favorably. It depends upon who operates and who takes care of the case afterward. The risk must be run, since this alone offers a way out, possible freedom, probable health. Wisdom forbids a mean choice to an enlightened mind. The operation is the thing.

PUBLIC HEALTH AND THE UNITED STATES GOVERNMENT.

THE Committee of the American Medical Association, appointed to get up a Department of Public Health, with a secretary who shall be a member of the Cabinet, has issued another circular to the members of the American Medical Association. Ignoring entirely the fact that there is now before Congress a bill which would help enormously toward the end which they themselves desire, it proceeds to say that its own bill is not yet strong enough to pass Congress. It then recommends that all State medical societies and all local societies pass resolutions favoring the doctrine in the bill, and that every doctor in the United States (one hundred thousand in all) shall address a private letter, in advocacy of said bill, to the Senators and Representatives in Congress. The circular is signed by Dr. Jerome Cochran, of Montgomery, Ala., chairman, and the seven other members of the committee. We are greatly in favor of securing some such plan as the committee wishes, but nothing is more certain than that such a bill cannot be passed for many years. Therefore, instead of wasting time in empty declarations, it seems to us it would be wiser if the committee would take hold and try and get what is practicable. One of the means to this end would be a conference between the committees of the American Medical Association and the New York Academy of Medicine, with an agreement on a joint bill.

FURTHER STUDIES OF THE MALARIAL PLASMODIUM.

WE referred recently to the subject of the value of the examination of blood in the diagnosis of malaria. In the *Indian Medical Gazette* for November, 1895, there is a report of further examinations of this character, by Dr. F. P. Maynard, surgeon-captain in the Indian Medical Service, and professor of pathology in the Medical College Hospital at Calcutta. Dr. Maynard says that from December, 1894, till April, 1895, he spent three or four hours daily examining the blood of fever cases for the malarial parasite. He, during this time, examined one hundred and twenty cases. Seventy of these, regarding which he had taken copious

notes, are analyzed and presented in a series of tables in the *Gazette*. The class of cases examined corresponded to the following clinical types:

Quotidian	26	Cases in which Laveran's bodies were found	6 times 1 " 5 " 0 "
Double quotidian ..	2		
Tertian	13		
Double tertian	1		
Quartan	1		
Remittent	17	Doubtful case in an out-patient	0 " 5 " 1 "
Irregular	10		
Total	70	Total	18 times,

i.e., 25.7 per cent.

As will be seen, the Laveran organisms are found in only twenty-five per cent. of the cases. The blood was nearly always examined between 10 A.M. and 1 P.M. Thirty-nine of the cases had not taken any quinine before examination. The technique of Dr. Maynard's method is given in full. He examined both fresh blood and specimens that were stained and dried, using a one-twelfth inch oil immersion. The methods which he followed correspond with those described and used in pathological laboratories here and in Europe and Dr. Maynard states that he has had the advantage of studying original specimens prepared by Marchiafava. Dr. Crombie, another Indian surgeon, in a discussion of Dr. Maynard's paper, said that he had been making similar examinations, and also had not, as a rule, found plasmodia.

These facts seem to deserve some attention from those who assert that the diagnosis of malaria can always be made by an examination of the blood. Either the examinations are not made correctly in India, or the blood is different, or the malaria is not due to the same kind of parasite as that which produces malaria in Europe and this country.

SHOULD DOCTORS WEAR BEARDS?

THIS important subject has been brought to the front again by Dr. F. A. Colby, of Berlin, N. H., in a letter to the *Boston Medical and Surgical Journal*. Dr. Colby admits that he wears a beard, and almost implies that he admires it. But he very candidly discusses the dangers and the propriety of continuing the practice. He cites a number of cases in which doctors, by reason of wearing beards, have carried the infection of diphtheria home, or have infected themselves, and he speaks also of the additional danger of carrying the scarlatinal infection when the physician wears a beard. The responsibility of the surgeon in this matter is particularly insisted upon. Some time ago the MEDICAL RECORD discussed this subject, as it thought, in a calm and dispassionate way, advising, not necessarily a total abolition of the beard, but restricting it to modest and sanitary limits. At that time, however, we received such severe criticisms from correspondents who had for years worn long and breezy whiskers, that it seemed wise that the subject be dropped. We shall follow with interest the progress of Dr. Colby's propaganda.

The Golden Jubilee of Dr. G. Lewin, the well-known dermatologist, was celebrated in Berlin recently under the auspices of the Dermatological Society.

CONFEDERATION OF STATE MEDICAL EXAMINING BOARDS.

IN the December number of the *Bulletin of the American Academy of Medicine* there is published the report of a committee appointed to arrange for the organization of the State medical examining and licensing boards of this country. The report is signed by Drs. McIntyre, Watson, Paine, and Potter. It states that since the system of State medical licensing had been adopted so extensively, and since it is probable that a similar system would soon be adopted in all the States of the Union, it is necessary that the examining boards of different States should take measures for approximating, as nearly as possible, uniformity as to rating and standards of acquirements. For this purpose a plan of organization is drawn up, consisting of a constitution, embodying nine articles. It is provided that the body shall be known as the National Confederation of State Medical Examining and Licensing Boards. The objects of this organization will be to have regular conferences of the members, the collection, compilation, and dissemination of information regarding State licenses, and, if desirable, the adoption of regulations for guiding the work of the confederated boards. The work of the confederated boards will be largely advisory, but such work will be much needed, and we trust that the proposed organization will be successfully accomplished.

News of the Week.

Obituary Notes.—Dr. M. A. Cremin, of New Haven, Conn., died December 28th, aged forty-three years. He was prominent in the municipal and educational circles of New Haven for many years. Dr. George H. Kirwan, aged forty-three years, died December 28th of appendicitis at his home in Wyoming Valley, Pa. Dr. W. H. Taylor, of Weldon, Ill., was shot and killed on December 28th by the postmaster of the town. Dr. Taylor had practised medicine in Weldon for twenty years, and had been identified somewhat with politics, being, at the time of his death, a member of the Illinois State Legislature. Dr. Thomas S. Powell died in Atlanta, December 30th. He was a native of Brunswick County, Va. He practised in Atlanta forty years, and founded the Southern Medical College of which he was President.

Hospital Sunday. The Hospital Association Work.—Last Sunday was Hospital Sunday. The contributions are reported to have been generous, but full returns of the amount received have not yet been published. The churches contributed last year to the Associated Hospitals \$23,100.69 of the \$58,208.29 collected for the Hospital Saturday and Sunday Association of New York. The denominations that contributed most largely to the fund were the Protestant Episcopal, which gave \$16,117.61; the Presbyterians, \$1,688; the Methodists, \$724.43; the synagogues, \$1,372.62, and the Reformed, \$959. The money collected for the Association is divided among the following thirty-eight hospitals: Mount Sinai, St. Luke's,

Ruptured and Crippled, German, Home for Incurables, St. Mary's, Eye and Ear Infirmary, Woman's, Infirmary for Women and Children, Ophthalmic, Ophthalmic and Aural, Orthopedic, Manhattan Eye and Ear, New York, Roosevelt, French Benevolent, Skin and Cancer College and Hospital for Women, Holy Comforter, Convalescent Home, Montefiore Home, Manhattan Dispensary and Hospital, Post-Graduate, Nursery and Child's, Colored Home and Hospital, Babies' Hospital, Cancer Hospital, St. Mark's Hospital, Mothers' Home of the Sisters of Misericordia, Flower Surgical Hospital, Isabella Heimath, Lying-In Hospital, St. Andrew's Infirmary, St. John's Guild Hospital, Beth Israel, and Lebanon. During last year these hospitals cared for 25,475 patients, of whom 19,535 were bed patients, and gave medical or surgical aid to more than 200,000 free dispensary patients. The total expenses for the year were \$1,046,109.25. They received from the city \$44,974.74 and got from paying patients \$270,752.10. The remainder they got from invested funds and contributions.

The Retirement of Dr. Geo. M. Gould from the editorship of the *Medical News* is a great loss to medical journalism in America. His sound judgment, impartial criticism, honesty of purpose, and scholarly attainments have won for him a reputation which has been well earned and is well deserved. In company with his host of friends we tender to him our best wishes for his future successes.

A Difference.—The Court of Common Pleas and the Superior Court are to be abolished—but the judges now presiding over them will become Supreme Court justices. They know how to do these things so much better in the law. When the hospital boards were abolished what were the old consultants made?

A Japanese Surgeon Honored by the Emperor of China.—The surgeon to the Mikado, who dressed the wound of Li-Hung-Chang after the attack made upon the Chinese plenipotentiary at Simonoseki, has at Li's request had the Order of the Double Dragon, Third Civil Class, conferred upon him by the Emperor of China.

The State Care of the City Insane.—Governor Morton, in his message of January 1st, recommends the formulation and passage of a law which shall give effect to measures for carrying out the plan of State care for the city insane. A bill to that effect was introduced by Senator Cantor and Assemblyman O'Grady at the first session of the Legislature.

Medical and Sanitary Legislation.—The following bills bearing on medical and sanitary matters were presented to the Senate during its first session, January 1st:

By Senator Brush—Providing for the abatement and prevention of nuisances in and about Newtown Creek in Brooklyn and Long Island City, and providing for sewers.

By Senator Lexow—Authorizing the Commissioners of the Sinking Fund of New York City to lease for ninety-nine years to the Hospital for Scarlet Fever and Diphtheria Patients land situated on the block

bounded by Avenue C, East River, Sixteenth and Seventeenth Streets.

A Cholera Conference.—It is reported that delegates have been appointed by the Italian and Austro-Hungarian governments, who will meet toward the end of the present month at Vienna for the purpose of discussing the sanitary measures to be adopted conjointly by both governments at the frontier, in case of an outbreak of cholera in either country.

For the Reinstatement of Retired Army Officers.—Under the bill of Congressman Shoup the Secretary of War is to appoint an Examining Board of five medical officers of the army to convene at Washington on January 1st and July 1st of each year to examine retired officers who apply for restoration to active service. If the report is favorable the President is authorized to restore any such officer "to the grade and rank he would have held" in his arm of the service had he not been retired, or "to appoint him to any other grade and rank" for whose duties he is thus found to be qualified. A bill for such restorations has also been introduced by Mr. McClellan into the House.

The Army Ration.—Secretary Lamont has appointed a Board to select an emergency ration for the army.

The Specialist in Female Diseases who has been sending his monthly reminders to physicians in New York and vicinity has disappeared under an indictment for committing abortion, and has forfeited his bail. Thus, for a time at least, our various office waste baskets will miss the savagely torn cards.

State Regulation of Medical Expert Testimony.—It is rumored that a bill has been prepared and will be introduced into the next New York Legislature aiming to change the present method of getting expert testimony. A "non-partisan board" is to be appointed by the Governor and confirmed by the Senate, and to this board all questions involving expert testimony will be referred. No one not a member of this board will be allowed to testify in any court except upon questions of simple fact. Regarding this plan the *Medical Age* says: "Regarding the bill which is to be presented to the New York Assembly, as now outlined it presents one very weak point. It is gotten up by a class of specialists, inasmuch as it is demanded the board shall be recruited from 'the ranks of expert alienists alone,' though the plea is added that these are to be 'men having a high ascertained qualification.' The qualifications of an expert, however, demand something more than mere ability to pass upon the sanity or insanity of an accused person. Alienists are no more competent to pass upon matters of expert pathology, microscopy, and chemistry than are other practitioners. Insanity is but one of the many pleas that require the careful attention of the court; further, the majority of so-called experts are men who have made their reputation on the basis of articles contributed to the medical press or to medical societies, and who consequently are likely to err in those points which are most familiar to the general practitioner."

An Opponent of Antitoxin.—An editorial appears in the *Journal of the American Medical Association* endorsing Mr. Lennox Brown's attitude of opposition to the use of antitoxin in the treatment of diphtheria.

Typhoid Fever is unusually prevalent in the State of Connecticut. Out of one hundred and sixty-eight towns in the State, the disease is reported in fifty.

Scarlet Fever has appeared in a somewhat epidemic form in the Mills Training School for Male Nurses.

Gray Hair and Cold Weather.—Dr. George W. Griffiths, in the *Journal of Cutaneous and Genito-Urinary Diseases*, reports the case of a man sixty-five years of age, who had had gray hair for eight years; for three years his hair had been perfectly white. He was exposed one night to severe cold and his eyebrows and whiskers got wet and were frozen stiff: it was found next day that his hair had turned black. The patient was shown to some medical men in Louisville. This beats the pilocarpine stories.

Kings County State Hospital.—Dr. Robert M. Elliott, of Rochester, has been appointed by the State Board in Lunacy Commissioners medical superintendent of the Kings County State Hospital for the Insane. Dr. Elliott was for five years assistant in the hospitals at Rochester. The State Commission first appointed Dr. T. E. Branford to this place, but he resigned.

Sir Henry Acland has been presented with a testimonial by the University of Oxford, in recognition of his services to medical science and hygiene. The memorial takes the form of a bust and of a fund of \$15,000.

The Chicago College of Physicians and Surgeons is making arrangements to amalgamate itself with the University of Illinois.

An American Missionary, Dr. A. J. Dyiaz, says *The Independent*, has organized seven Red Cross hospitals in Cuba.

Prof. Pierre Ch. Fauvel, a distinguished French physician, died in Paris on December 17th, aged sixty-six years. He was especially well known for his writings upon diseases of the throat and nose.

Dr. Hugh B. Davis, of Wellsboro, Pa., died on December 19th, aged forty-five.

A Case of Acute Traumatic Tetanus was recently treated by antitoxin serum by Dr. Aldren Turner in the West London Hospital. The case recovered, and is reported in detail in *The Lancet* of December 7th.

Tubercular and Tuberculous.—*The Lancet* calls attention to the indiscriminate and incorrect way in which these two words are used. The adjective "tuberculous" should, it thinks, be applied only in connection with the specific infectious process known as "tuberculosis." The adjective "tubercular" has a purely anatomical meaning, and is to be used only as a means of anatomical description, and signifying "nodular." Our contemporary laments the fact that the two adjectives are used so indiscriminately, and

begs that writers will be more careful in the future. As a matter of fact, the word "tubercle" is rarely used now, except in connection with the specific infectious disease of tuberculosis, and practically it might be well to remember that the adjective "tuberculous" is the one that is almost always to be used.

Medical Club Practice in France.—The country doctors of France, who undertake club practice, have, it appears, the worst time of all. Some of them make an agreement with the village to attend its paupers for the sum of fifty francs a year.

M. Lannelongue, professor of surgery in the faculty of medicine in Paris, has been elected to the Académie des Sciences, in place of the late Professor Verneuil.

Thyreo-Antitoxin.—Dr. Fränkel has obtained from the thyroid glands a substance which he calls "thyreo-antitoxin," and to which he gives a special formula $C_6H_{11}N_3O_2$. The substance is inodorous and tasteless, and it is inferred that it contains the active principle of the thyroid, because it produces rapid emaciation.

Small-pox Hospitals as Nuisances.—The High Court of Justice, England, has just rendered a decision with regard to the question as to whether or not a small-pox hospital is a nuisance. Arrangements had been made to build a hospital upon a lot which was surrounded on all sides by a common on which cattle fed and children played. Although thus isolated, the neighbors brought an injunction against the hospital management, and tried to prevent the erection of the buildings, on the score that it would be a source of danger. The prosecution got a number of experts to testify that small-pox could be conveyed for long distances by air. But the judge refused to grant the injunction, and allowed the hospital to be built.

The Kinetograph and the Clinic of the Future.—A French journal suggests that by the use of the kinetograph the clinical work of the future can be very much simplified. Kinetograph illustrations of clinical cases may be prepared and distributed throughout the country by means of university extension organizations. In this simple way, post-graduate lecturers could talk at a kinetograph carefully prepared lectures, at the same time exhibiting patients to the revolving discs of the photographic machine; the results could be sold in regular lots at so many dollars per dozen.

New Journals.—Announcement is made of *The Journal of Experimental Medicine*, a periodical to be devoted to the recording of original investigations in physiology, pathology, bacteriology, pharmacology, physiological chemistry, hygiene, and practical medicine. The editor will be Dr. William H. Welch, professor of pathology in the Johns Hopkins University, who will be assisted by a board of twelve associate editors. Another new journal is *The State Hospitals Bulletin*, which will contain reports of clinical and pathological work in the New York State hos-

pitals for the insane and in the laboratories connected with them. All the articles in this periodical will bear some relation to hospital work, and, as far as possible, will be in the nature of a report of observations in the hospitals, with deductions based thereon; no essays upon general medical subjects, not specially related to insanity, will be admitted, although there will be no prohibition of free treatment of any subject reported upon. The same treatment can be accorded a subject that is given to any article prepared for other medical journals, provided only that the essay is based primarily upon observations and experiences connected with asylum work. *The Bulletin* will be edited by a staff of hospital superintendents, the editorial committee for the present year being Drs. P. M. Wise, C. W. Pilgrim, and S. H. Talcott.

The Northwestern Ohio Medical Association held its fifty-first semi-annual meeting at Findlay on December 12 and 13, 1895. The following officers were elected: *President*, Dr. Charles Graefe, of Sandusky; *Vice-Presidents*, Dr. Slocum, of Defiance; Dr. Philips, of Belle Centre; *Secretary*, Dr. J. B. Baker, of Findlay; *Assistant Secretary* and *Treasurer*, Dr. Gehrett, of Deshler. The next meeting will be held at Defiance.

The Marion County (Fla.) Medical Society held its annual meeting on December 9th, at Ocala. The following officers were elected for the ensuing year: *President*, Dr. W. V. Newsom; *Treasurer*, Dr. W. R. O. Veal; *Vice-President*, Dr. D. A. Smith; *Second Vice-President*, Dr. T. J. Myers; *Secretary*, Dr. R. P. Izlar. Various papers were read and discussed.

The Subathu Leper Asylum.—Dr. M. B. Carleton, Superintendent of the Leper Asylum at Subathu, North India, writes that two Europeans have recently been received into the asylum, one of them a lad of ten years. Three more applications have been made, but for want of room and funds they have been refused for the present. There is need of money for the erection of a cottage ward.

Supply of Sea-Water to London.—A company has been organized with the object of providing London with a supply of sea-water direct from the Channel. It is held that there would be a great economy in using this instead of fresh water to flush the sewers.

The Chalfont St. Peter Epileptic Colony.—A new home to accommodate eighteen men was recently added to the Chalfont Colony in England. This colony was opened in July, 1894, with nine colonists. In August, 1895, the committee were able to take thirty-six, and it is hoped that within a year the numbers will be doubled. The colonists have been employed mainly at market gardening, and a few of them at occupations, such as carpentering, which they followed before their admission. Lack of funds has up to the present hindered the provision of other employments such as basket-making, netting, rope-making, etc., which will provide more variety and allow more scope for differences of capacity on the part of individual colonists. Hitherto, strangely enough, there has been

no medical man resident at the colony, but the committee have now determined to erect a building for a resident medical officer.

Hospitality of New York and Paris Surgeons.—At the recent Congress of the French Surgical Society Dr. Bousquet, of Clermont-Ferrand, complained of the unsympathetic attitude of the Parisian hospital surgeons toward the members of the Congress, in that they were far from cordial in their invitation to strangers to attend their operations or visit their wards. The general secretary admitted that the complaint was fully justified, and said that he had done his best to remedy the defect, but, unfortunately, could not succeed. He compared this apparent churlishness with the reception of visiting surgeons in New York. When a visitor arrived in that city and manifested a desire to witness operations, the utmost *empressement* was exhibited to afford him every information by telegraph. No matter where he might be sojourning, every morning messages would arrive containing detailed statements of all the operations it was proposed to perform that day, together with time-tables and route instructions. It would be very easy for the Parisian surgeons to imitate their New York *confrères*, and thus remove the grievance to which Professor Bousquet alluded. All that was necessary was a little good-will, but, unfortunately, that was precisely what was not forthcoming. Possibly these gentlemen had very good reasons for their action, or inaction, but if so it was strange that similar reasons should be non-existent across the Atlantic.

Sir Joseph Lister has been elected President of the Royal Society, succeeding Lord Kelvin. The only other surgeon who ever held this office—an honor prized above all others by British scientists—was Sir Benjamin Brodie, who was elected about 1860, after having been a fellow of the Society for half a century.

Dr. Andrea Verga, for many years Professor of Medico-Psychology at the Ospedale Maggiore of Milan, died on November 21st. He was born on May 30, 1811, at Treviglio, and was educated at the University of Pavia.

Co-Education in Hungary.—The Emperor Francis Joseph has issued a decree which provides that women at the Hungarian universities may now be admitted to the medical and philosophic faculties, and thus enabled to become chemists, doctors, and professors. There is, however, a saving clause which renders it necessary that permission be first obtained from the Minister of Justice.

Professor Struthers has been elected President of the Royal College of Surgeons of Edinburgh.

How to be a Centenarian.—Sir Benjamin Ward Richardson still gives it as his fixed opinion that every man and every woman should attain the age of one hundred. According to Sir Benjamin, the would-be centenarian must have a blond complexion, with hazel eyes, light-brown hair, and reddish cheeks. He must never smoke nor drink, must eat very little meat, and he must not work by artificial light.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, December 19, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT.

"Vaginal Versus Abdominal Section."—DR. W. M. POLK read a paper with this title. He said that the advocacy of the vaginal method had been so persistent that it could not be ignored. Its cause had been, however, injured by the extravagant claims that had been made in its behalf. It was folly to talk of it driving abdominal section from the field, for there were certainly conditions which could be much better met by abdominal section. Even though vaginal section should diminish the frequency of abdominal section by as much as one-half or two-thirds, he still felt that it would ever remain subordinate to abdominal section. It was evident, therefore, that wherever the boundary line between these two methods should be eventually drawn, it must be made movable. Dr. Polk said that at present he believed that out of one hundred cases, about seventy-five would be found suitable for the vaginal operation. Excluding vaginal hysterectomies done previous to 1882, he had performed about seventy-two vaginal sections for every disorder for which it had been advocated.

The various conditions considered favorable for vaginal section were next taken up in order. Among these conditions were: explorations of the pelvis, operations on the displaced uterus with adherent uterus and appendages, intra-ligamentous cysts, small ovarian cysts, fibroid tumors, acute inflammations of the appendages associated with acute peritonitis with involvement of Douglas's pouch, extra-uterine pregnancy, pelvic hæmatocele, puerperal metritis, destructive diseases of the appendages from inflammatory, tuberculous, and cancerous processes, and so-called conservative operations on the appendages. Vaginal section was particularly applicable to collections of pus fixed by adhesions. All tumors which were small enough to be contained, wholly or in part, in the pelvis, were suitable for the vaginal operation. While it was true that many tumors wholly outside of the pelvis could be best treated by abdominal section, it was equally true that many of them could be reached by the vaginal route, provided it were proper to remove the uterus. Extra-uterine pregnancy, the author said, was a condition which prior to rupture one could always select to reach through the vagina. The tumor was reached in this way without difficulty, although sometimes it might become necessary to remove the uterus. After the placenta had been fully formed, and if the child was alive, the supra-pubic route was preferable, but where the child was dead, the vaginal method would meet every indication. The vaginal method offered the best means of checking the ravages of acute inflammation, and of doing plastic operations on the uterus and adnexa. It was the best operation for suppurative disease of the adnexa. All soft fibroid tumors situated below the level of the umbilicus can be removed by vaginal section, and likewise all hard fibroids situated largely in the pelvis, though extending considerably above the pelvic brim; but hard fibroids situated wholly above the pelvic brim, and so large as to forbid their removal by being drawn into the cavity of the pelvis, are difficult of extraction by the process of morcellation.

The conditions favorable for abdominal section are: Explorations in the false pelvis and above the false pelvis; visceral adhesions in the false pelvis or above; cysts with long pedicles or gelatinous contents situated wholly above the pelvic inlet; ruptured extra-uterine

pregnancy in which bleeding is active; extra-uterine pregnancy with the tumor wholly above the brim and the child alive; cancer of the ovaries; large and hard fibroids mainly filling up the abdominal cavity and extending above the line of the umbilicus.

The chief objections, the speaker said, that had been raised against the vaginal section were: (1) Removal of the uterus and appendages by vaginal section was more difficult; (2) vaginal section must depend to a certain extent on the size, shape, and condition of the pelvis; (3) the operation was liable to be incomplete; (4) the viscera were more likely to be injured; (5) sepsis was more difficult to prevent; (6) hernia would occur; (7) the sloughing incident to the use of the clamp. On the other hand, it was claimed that it was as safe as abdominal section, that recovery was more rapid, and there was less likelihood of hernia and intestinal adhesions.

DR. E. W. CUSHING, of Boston, said that there could no longer be any doubt that the resources of our art had been wonderfully augmented by the introduction of morcellation of the uterus. The method had extended in spite of strong opposition, and now numbered among its advocates some of those who had at first most bitterly opposed it. There was, of course, still considerable opposition, and there was a not inconsiderable number of surgeons in this country who still believed with one of our eminent surgeons that vaginal hysterectomy for pus tubes was "blind, ignorant, and cowardly." Indeed, the speaker said, he had felt at one time very much the same way himself, but a careful study in person of the work of eminent surgeons who were doing vaginal hysterectomy by morcellation had won him over to their ranks. As many of our surgeons were now thoroughly alive to the evil of leaving the uterus behind, the question at the present time was really between total abdominal and total vaginal removal of the uterus and appendages. By the introduction of morcellation the operation had become practically a new procedure. By splitting the uterus in half, and by successive divisions of these halves, the uterus gradually descended and rotated anteriorly, thus bringing into sight any adhesions that might exist. The vessels were controlled by powerful clamps, applied under the guidance of both sight and touch. In this way the uterus could be safely and speedily removed with a minimum of shock, and that, too, even when the organ was bound down by adhesions or was the seat of a myoma. By this method of operating, all fibroid tumors not larger than a cocoanut could be successfully removed with far less shock to the patient than from an abdominal section. The ease and safety with which the uterine appendages could be removed, or intestinal adhesions separated by the vaginal route, could hardly be credited by one who had not had the good fortune to witness the performance of the operation by a master hand. After the removal of the uterus, whatever part of the tube presented, could be brought down and enucleated under the guidance of vision. Dr. Cushing said that in his opinion the vaginal operation was to be preferred in cases of uterine myomata of moderate size; but a narrow outlet to the bony pelvis, or a tumor over five inches in diameter, constituted a serious contraindication. Unless expert in performing the vaginal operation, it should not be undertaken where there were many intestinal adhesions. He thought it was generally admitted that the vaginal operation was best in cases in which there were large collections of pus from tubo-ovarian abscesses or from suppurating hæmatocele where the pus was roofed over by dense adhesions of bowel and omentum, particularly if the patient were much exhausted. As the uterus was usually diseased in cases of pyosalpinx, it should be removed when this could be done without

adding to the risk. If, however, there was apparently no pus, and it was probable that the uterus was bound down by firm adhesions, he was not yet convinced of the superiority of the vaginal operation. The advantages of the vaginal operation were diminution of shock, freedom from abdominal wound and scar, and freedom from the liability to hernia.

Dr. Cushing then gave a demonstration, by means of lantern-slides, of the various steps in the modern vaginal operation.

Dr. W. T. Lusk referred to the circumstances that had led to his conversion to the vaginal method. When it had been first proposed in Brussels, in 1892, there had been so many other important questions under consideration that he had received the suggestion with considerable impatience; but his attention having been attracted by the wonderful rapidity of recovery of cases operated upon by the vaginal method, he had given the subject more consideration, and finally availed himself of an opportunity to personally watch the work of such men as Péan, Pozzi, Ségond, and Jacobs. After seeing Ségond remove by morcellation a uterus as large as one at full term, he had become convinced of the advantages of the pelvic route and of its capabilities.

In removing fibroids by morcellation, he said, we found that, in spite of the length of time consumed in the operation, there was scarcely any appreciable effect upon the patient. The vaginal operation was certainly safer than the abdominal one in cases in which there was a double pyosalpinx and the tubes were removed after the uterus. The speaker said that he had hesitated longest about adopting the vaginal method in conservative operations on the tubes and ovaries, and he still felt that the abdominal route was the better one except where a large anterior incision is employed. In the latter case it was possible to operate by the vaginal method with no more shock than would be associated with an amputation of the cervix. Experience had shown that already the women themselves were insisting on the adoption of the vaginal method wherever possible. In making the change from the abdominal to the vaginal route the surgeon should go slowly, employing the vaginal method only in the simpler cases at first.

Dr. BALDY, of Philadelphia, said that he was not in sympathy with the views that had been just advanced regarding the vaginal operation. In his opinion there was just as little shock from the abdominal as from the vaginal operation, and in a given class of cases the surgeon could do his work infinitely better and with less risk to the patient by the abdominal route. It had been argued that by the vaginal route the peritoneal cavity was not so frequently opened, but this was not in accordance with the facts, as there was hardly one case in a hundred in which the peritoneal cavity was not opened just as much by the vaginal as by the abdominal method. He also thought that by abdominal section and the use of the Trendelenburg position much better conservative surgery could be done on the ovaries and tubes than by the vaginal method in which the surgeon was deprived of the aid of vision and must rely almost entirely on the sense of touch. One of the great arguments advanced in favor of the vaginal operation was the diminution of shock, but in his experience shock was not a great element in pelvic surgery. The avoidance of hernia was another argument, but hernia was getting to be a rather rare complication of abdominal operations at the present time, and the vaginal operation was occasionally followed by this complication. If it should occur, it was evident to any surgeon that it was a much more difficult condition to treat than abdominal hernia. It should not be forgotten that comparatively few operations by the vaginal route had been done in

this country, and that, therefore, there could not be very many vaginal herniæ on record. The proportion of fistulæ that had been reported as following vaginal hysterectomies was truly alarming; there was hardly a vaginal hysterectomist who did not include fifteen or twenty fistulæ in his list of such operations, and some of them had commented on the difficulty of curing these fistulæ, and the necessity at times of resorting after all to abdominal section. It need hardly be said that a secondary operation was much more difficult and dangerous than a primary section. He did not believe that these fistulæ were as rare after the vaginal operations as had been asserted. Again, the ureter was very liable to be injured in the vaginal operation without the surgeon being cognizant of the fact. In his own experience he had wounded the ureter three times in the abdominal operation, and had discovered the injury only just in time to repair it before closing the abdomen. He had never had the fortune to see a vaginal hysterectomist do a complete operation, and moreover even an expert operator usually took nearly twice as long to do the operation that he would if he had adopted the abdominal method. This prolongation of the etherization was a serious matter. Lastly, it had been repeatedly urged that the vaginal operation was followed by a much more rapid and easy convalescence, but to this he must take exception. The abdominal operator believed that his patient was better off in bed for four weeks, irrespective of her recovery surgically, while the vaginal hysterectomist allowed his patient up as soon as she was surgically well. In view of the facts he had presented he felt that the comparison was in favor of abdominal operations, sentiment not considered.

Dr. E. B. CRAGIN said that he thought all pelvic surgeons must have noticed depression after abdominal operations, and that this depression—call it "shock" or not—was not so great after vaginal operations. He could not agree with Dr. Baldy that the vaginal operation was not suitable for cases of large pelvic intra-peritoneal abscesses. Since last March he had done fifty-five vaginal cœliotomies, of which forty-two were for diseased appendages. He admitted that there was more danger of injuring the rectum in the vaginal than in the abdominal operation, but the latter was evidently free from danger, as Dr. Baldy confessed to having had three injuries to the ureter. He thought that the cases operated on by the vaginal method were better, not only immediately after the operation but six months later, and he was confident that vaginal hysterectomy was an operation that had a future.

Dr. CHARLES P. NOBLE, of Philadelphia, said that the favorable points of the vaginal operation had been brought forward, but only in very general terms. There was but little doubt that the mortality was lower by the abdominal route, but it was so low by both methods, that this was no cause for a quarrel. Dr. Kelly had had one hundred and seven abdominal hysterectomies for inflammatory conditions without a death. His own experience did not bear out the allegation so frequently made, that there was much poor health following abdominal operations, for certainly five per cent. would cover this morbidity in his cases. Most vaginal operators reported about ten per cent. of incomplete operations, and this should be contrasted with the small number of infected pedicles after abdominal operations. Bowel and bladder fistulæ were apparently much less frequent in connection with abdominal operations, and the abdominal operator had a decided advantage over the vaginal operator in that he could at once close the rent.

The speaker said that he also felt that the rapidity of convalescence after vaginal hysterectomy had been greatly exaggerated. His own cases of this kind had

been as long in his hospital as those of abdominal hysterectomy—indeed, he thought that convalescence was much more rapid after the abdominal operation. Most of these patients were broken-down women in whom several weeks of rest proved a valuable factor in restoring their general health. Hence, the matter of the time spent in bed after the operation was in practice a trifling one. The abdominal route certainly offered superior facility for dealing with complications arising during the operation, and also for the control of hemorrhage. He had recently seen two cases in which appendicitis had developed shortly after labor. Had the operation been performed by the vaginal route it would have been necessary to remove the uterus before the true condition could have been properly treated. The great argument against the abdominal operation—the liability to hernia—seemed to him to have but little force, for he had recently reported two hundred cases in which by means of buried silkworm-gut sutures he had successfully treated this condition, with not a single relapse, so far as he had been able to ascertain.

He was prepared to believe that anterior colpotomy might be suitable for the extraction of small fibroids, but for larger tumors he would certainly prefer abdominal section to morcellation. He also believed that the abdominal route was preferable for cases of tubal pregnancy except in the few instances in which there was a suppurating hæmatocele. By operating from below one would be apt to sacrifice many ovaries unnecessarily.

In conclusion, the speaker expressed the opinion that operations through the vagina were chiefly applicable to large pelvic abscesses, and to cases in which, owing to excessive fat, it was objectionable to operate through the abdomen.

DR. H. J. BOLDT said that the remarks that he desired to make in connection with this discussion were based on a large experience with both the abdominal and vaginal methods. Ovarian tumors of considerable size could be removed per vaginam, provided the neoplasms were movable. The vaginal operation was applicable to cases of tubal pregnancy in which rupture has not occurred, or in which the hemorrhage has ceased after rupture. Fibroids which do not extend more than three or four fingers above the symphysis might be removed through the vagina. The submucous and interstitial tumors were most easily operated upon by this method. For other fibroid tumors, and the neoplasms occurring in virgins, abdominal hysterectomy was preferable. Complicated cases of pelvic abscess were rarely curable except by the removal of the pelvic organs, and the ultimate result was much better when this was done per vaginam. It was possible to do a complete operation in almost every instance by patient and careful work.

The speaker said that he could not but feel that a more satisfactory diagnosis could be made by a free abdominal incision than by the vaginal operation. The risk of injuring the ureters and intestine was about the same in both methods. He had never met with vaginal hernia in the large number of vaginal operations that he had done.

DR. H. N. VINEBERG said he believed that he was the first to introduce the operation of vaginal incision, which was the forerunner of vaginal section for conservative work. He considered the vaginal method particularly applicable to this class of cases, and as retroversion was liable to be associated with disease of the adnexa, the method was obviously desirable as it allowed of the retroversion being relieved at the same time by suture of the organ to the vaginal wall. He could not agree with Dr. Noble that, by the vaginal method, perineorrhaphy and other similar operations could not be performed at the same time. He

believed that in almost every case the peritoneal cavity was opened in vaginal operations.

DR. PAUL F. MUNDE said that he did not believe the majority of pelvic surgeons in New York City were in favor of the vaginal route. He had removed the uterus per vaginam for cancer in twenty-seven cases, with twenty-four recoveries, but as he had obtained equally good results more easily by the suprapubic method, this latter method he would employ in the future. There was certainly no more shock by the abdominal method. On comparing vaginal and abdominal hysterectomy for the removal of fibroids, and taking into consideration the number of instruments in the field of operation and the difficulty of controlling the hemorrhage, he was forced to the conclusion that the vaginal route was like night and the abdominal route like day. He had long maintained that the vaginal route was the best for the treatment of all fluid accumulations, and many were now coming to his way of thinking. He would not remove ovarian tumors or fibroids through the vagina unless they were small or unusually accessible by this route.

DR. E. E. TULL presented a specimen to illustrate the completeness that might be attained in the vaginal operation. He had done fifty vaginal operations with two deaths. Both deaths were entirely attributable to accidental causes, such as negligence of the nurse or disobedience of the patient. He saw no occasion to use many clamps or ligatures in this operation; he had recently extirpated a ten-pound tumor, using only one clamp and two ligatures.

DR. W. GILL WYLIE said that whereas he had done one thousand five hundred abdominal operations he had had only about one hundred vaginal operations. Of the vaginal operations only one had died, but he attributed this excellent result largely to the fact that the vaginal method had been used only in favorable cases.

DR. POLK, in closing the discussion, said that there appeared to be a pretty general agreement regarding the greater ease of operating by the abdominal route, but the easier operation is not always the better one for the patient. The peritoneal cavity was as likely to be entered from below as from above, and the apparent slowness of operating was not so marked as it at first seemed, because one must take into account the time consumed in suturing the abdomen. He was not thoroughly decided in his own mind regarding which was the better operation for cancer, but he was inclined to think that we should operate through the abdomen, and add to the operation of Freund the removal of the broad ligament and all infected glands.

Those who had taken part in this discussion had apparently failed to grasp the great underlying principle, viz., that pelvic disease usually begins in the bottom of the pelvis in close relation to the vagina, and that by incision of this structure one could safely operate at a very early stage, and so prevent much of the usual involvement of pelvic structures.

DR. J. BLAKE WHITE, in accordance with the by-laws, gave notice that at a future meeting of the Academy he would ask for the consideration of a series of resolutions deprecating the action of the Commissioners of Charities and Correction in regard to abolishing the consulting board of Charity Hospital and the consulting and visiting boards of the other city hospitals, and their new plan of making medical appointments to positions in these hospitals.

SECTION ON GENERAL MEDICINE.

Stated Meeting, December 17, 1895.

ADOLPH ZEH, M.D., IN THE CHAIR.

Case of Splenic Myelogenous Leukæmia, Not Cured by Bone Marrow.—In presenting the case DR. CHARLES E. NAMMACK read a paper which he had

published in the *MEDICAL RECORD*, December 14, 1895, p. 858.

In discussing the paper by Dr. Nammack Dr. MAURICE MANGES said that he had had a case with splenic myelogenous leukæmia which when put on the treatment with bone marrow had grown worse. When the patient was put back on treatment with arsenic he improved, but grew worse again when returned to the treatment with bone marrow. The patient died in six months. Dr. Manges said he had used bone marrow in the treatment of a case of pernicious anæmia and it had done no good.

Dr. THOMAS S. SOUTHWORTH exhibited stained specimens of leukæmic blood and also fresh specimens taken from the leukæmic patient during the evening.

Urinary Analysis.—F. E. SMITH, PH.D., read a paper entitled "Notes on Urinary Analysis. 1. Methods used by the writer for detecting traces of albumin in urine. 2. Standards in quantitative urine analysis" (see p. 13).

In discussing Dr. Smith's paper Dr. MANGES said that in using Heiler's test it was well to let the test-tube stand for four or five minutes, for the white band might not appear at once.

Dr. WOOD, of Boston, had called attention to the fact that by the use of a larger vessel, in which there was a larger surface contact of the nitric acid and the urine, a better effect was secured.

Dr. STEWART, of Philadelphia, had called attention to the fact that, in using some forms of filter paper containing a certain amount of organic matter, enough albumin could be secured from the paper to respond to the test. Dr. Manges found trichloroacetic acid utterly useless for practical purposes, for it was too delicate a test for working routine. The tests by heat, hot nitric acid, and cold nitric acid were all easy and useful.

Case of Enlarged Spleen, etc.—Dr. R. C. NEWTON presented the history of a patient as follows: Patient a native of Poland, laborer, married, and thirty years of age. He was admitted to Mountinside Hospital, Montclair, N. J., September 12, 1894, with a painful and indurated swelling in the left ischial region. The patient was in great pain. The mass was poulticed, and on September 21st this was opened by deep incision on both sides of the rectum. Large quantities of dark fetid and clotted blood were evacuated. The cavity was thoroughly washed, packed with iodoform gauze, and for three days a great deal of hemorrhage, mostly by oozing, came from the wound. All the tissues about the rectum were broken down, so that a large irregular cavity nearly surrounded the bowel. A large tumor was noticed on the left side occupying a considerable portion of the abdominal cavity. This proved to be the enlarged spleen. The patient was put on potassium iodide, but this had to be discontinued on account of gastric disturbance. Tonics, quinine, and supporting diet were then resorted to. Examination of the blood revealed the following: white corpuscles one hundred and seventy-five thousand, and red corpuscles between three and four millions per cubic millimetre. The urine was normal. The patient denied syphilis and intemperance. He gave an indefinite history of malaria, and at one time had had two abscesses near the axilla which yielded to surgical treatment. The peri-rectal lesion healed; another large hæmatoma appeared in the deep muscles of the right thigh, and the incision of this nearly led to a fatal hemorrhage. The patient improved, but though under observation for six months there was no diminution in the size of the spleen. Being anxious to return to his family in Poland he was discharged from the hospital and lost sight of.

Progress of Medical Science.

Mercury Oxycyanide as an Antiseptic.—According to Drs. Monod and Macaigne, laboratory experiments have shown that the antiseptic power of a 1:200 solution of mercury oxycyanide is equal to, if not greater than, that of a 1:1,000 solution of corrosive sublimate. From the results obtained in upward of four years of hospital and private practice, the authors have come to the conclusion that mercury oxycyanide may be advantageously substituted for mercuric chloride in surgical practice. In accord with Tarnier and Vignal, they have found that a 1:200 solution of mercury oxycyanide, fully as well as, if not better than, a 1:1,000 solution of mercuric chloride, prevents cultures from developing, kills the microbes already developed by cultures, and sterilizes an infected body. To strengthen the evidence, they have been careful not to employ in their experiments pure cultures of streptococci or staphylococci devoid of spores, and consequently presenting but a feeble resistance, but dust from hospital wards, containing various microbes, such as the bacillus pyocyaneus, streptococcus, bacillus coli communis, and particularly a microbe resembling the bacillus anthracis and provided with spores, which resists a temperature of 212° F. The authors claim to have never met with symptoms of serious intoxication from the solution referred to. It should, however, not be employed for irrigation when there is reason to fear that the injected liquid may be retained. The fact that mercury oxycyanide does not attack steel instruments is also of great practical importance, seeing that it thus becomes possible to employ a single antiseptic agent for all purposes in the course of an operation.—*La Semaine Médicale*.

The Occurrence of Secondary Rashes in Scarlet Fever.—Dr. A. Griffith, of the Bagthorpe Fever Hospital, Nottingham, remarks that, among scarlet-fever patients, during convalescence there seems to be a proneness to the return of a scarlatiniform rash when the temperature of the body rises from any cause. It frequently accompanies an acute amygdalitis or rhinitis, or the onset of acute nephritis, and this even in adult patients, so that the diagnosis of reinfection cannot be made from the rash alone, but it is necessary to have other evidence in favor of a scarlatinal origin (*New York Medical Journal*). When the rash is attended by all the symptoms of scarlet fever, and with no other possible explanation, we encounter a new difficulty in deciding whether the attack is primary or secondary, especially if we have not watched the patient from the beginning of the first illness. The absence of desquamation is not of much help, since, as is generally admitted, there are many cases of scarlet fever in which desquamation does not amount to more than a furfuraceous powdering, and unfortunately, if we wish to reconsider the first diagnosis after the lapse of three or four weeks, we find little else to base our conclusions upon. On the other hand, says the author, if at the end of four weeks we find abundant membranaceous peeling, we are justified in affirming that the first illness, at any rate, was scarlet fever, and we are in a position to consider whether the second is a return of the same. As far as his experience in the Nottingham Fever Hospital goes, he says, all the patients who have presented a scarlatiniform rash some days or weeks after admission to the wards may be arranged in three groups: 1. Those whose illness presented all the signs of moderate or severe scarlet fever, with a high temperature (103° F. or more), keeping up at nearly the same height for at least three evenings, and in whom there was no good evidence of a previous attack of that disease. 2. Those in whom the

illness resembled scarlet fever in nature, the rash lasting from twenty-four hours to four days, with sore throat and general constitutional disturbance, the rise of temperature being not so great as in group 1, but either high at the beginning, with a steady, gradual fall, or remaining at a lower level (100° or 101° F.) during the continuance of the rash and falling as the latter faded, and in whom there *was* clear evidence of genuineness of the first attack of scarlet fever. 3. This includes all those who had a rash lasting from twelve to twenty-four hours, in some accompanied by little constitutional disturbance and a high temperature for a few hours only; in others with the onset of an acute inflammation of throat, kidneys, or other organs; while in other cases the question of a relapse was entertained, the patients presenting some of the symptoms, but in a very mild form. Those in the first group, says Dr. Griffith, have been considered as primary attacks of scarlet fever; the second group are those discussed here as relapses, or second attacks; while the third are omitted as doubtful. Out of about two thousand patients admitted for scarlet fever, there were fourteen who had suffered from what may be considered as second attacks of the fever. In the first four cases there was good desquamation after the primary attack, and the second attack either was typical and severe or was followed by a second abundant desquamation. In the next four cases there was desquamation after the first attack, and the second was mild. In the next three the first attack was mild, and the second more severe, accompanied by good desquamation. In the last three both attacks were mild, and neither was followed by more than a powdering of the skin. If, he says, the evidence for these last is not all that could be wished, it may be noted, at any rate, that they were passed into the fever wards as genuine, and remained there for some weeks; that the later illnesses were mild, and the temperature charts did not resemble the usual type of mild scarlet fever. We cannot draw any inference, says the author, from so few cases as to the most frequent age or as to the interval elapsing before reinfection occurs, the only noteworthy point being that where the interval was short the first attack was of a mild character. There seems, he adds, to be a special liability to nephritis after a second attack, though not ensuing immediately. In one case, in which there had been acute nephritis with the first illness, the albuminuria, which had ceased for a week, again became serious with the second rash. Three of the patients were discharged within four weeks and three in five weeks after the onset of the second rash, with no ill effects to their friends, so that possibly the duration of infection is less than in a first attack. All were kept until the later desquamation was complete. It may be thought, says Dr. Griffith, that these cases bear some relationship to the so-called secondary sore throat of scarlet fever. His experience, however, is that the types of illness in the two are quite different. In the latter the throat affection is generally an acute quinsy, and the temperature corresponds to it and falls as it gets better. In the secondary rash cases there *is* a sore throat, but it is only a part of the illness, the temperature corresponding to the rash. If, he says, this argument is accepted, and these later rashes are to be explained as has been indicated (and the experience of other large isolation hospitals agrees, he thinks, with his), the question arises as to whether the illness is due to self-infection, being properly termed a relapse or recrudescence, or whether it depends on the presence of other patients in the same ward, some of whom may have fever of a more virulent character. The experience of medical men in private practice should help us, he thinks, as to the occurrence of relapses in scarlet-fever patients nursed singly at home.

Meanwhile, it is not difficult to imagine that, in a ward containing twelve or twenty patients, even with two thousand cubic feet of air space each, the amount of infection is very large, the virulence being possibly increased by aggregation as well as by the uniform temperature of about 60° F., or to suppose that those who have had mild attacks from a small dose of poison in the first place, rather than from their insusceptibility, may be insufficiently protected against a larger dose of a more virulent infection. If this is the correct explanation, says Dr. Griffith, it would point to the inadvisability of aggregating fever cases in large wards, and still more to the fault of the usual plan of placing mild and medium, if not severe, cases in the same wards and in the hands of the same nurses. It is to be hoped that as the experience of isolation hospitals becomes more complete, and the facts gained in them are collected and compared, we may be able to come to some conclusion on a point of such practical importance.

Iodine in Diseases of Children.—Dr. J. Comby asserts that iodism is of exceptional occurrence in children, and the younger the patient the less is the liability to this accident. The immunity is presumably dependent upon the rapid elimination by the kidneys, salivary glands, and all the emunctories. In children, as in adults, iodine and the iodides find their special application in syphilis. Hereditary syphilis in the newborn agrees with the acquired tertiary form in demanding the use of the alkaline iodides. The potassium salt is of value not only in undoubted syphilis, but in cases where a syphilitic basis may be suspected, as coryza, obscure lesions of the buttocks, pseudo-paralysis, etc. Furthermore, even in the absence of any eruption upon the skin or mucous membranes, if the babe is cachectic without reason, if it does not thrive, Potain advises that it should be treated as a syphilitic. When a child is born before term and the mother has had one or more abortions, has lost one or more children at a tender age, it is prudent to adopt antisyphilitic treatment. Convulsions without apparent cause, meningeal manifestations, etc., indicate the administration of potassium iodide. At a later period, children with subcutaneous gummata, osseous tumors, or perforation of the soft palate improve upon the use of the same remedy. Dr. Comby has found iodine efficacious in several cases of paroxysmal hæmoglobinuria occurring among children. Potassium iodide is indicated in diseases allied more or less indirectly to syphilis (the parasymphilitic affections of Fournier), in hydrocephalus, for example; in cerebral tumors, chronic meningo-encephalitis, partial epilepsy, etc. In grave cases it is well to associate the mercuric iodide, as in syrup Gibert. If the success of iodine medication be particularly brilliant in syphilitic cases the same method is of undoubted service in many other affections to which children are subject. Among lymphatic, scrofulous, and anæmic children who suffer from glandular engorgements, tonsil hypertrophy, and pharyngeal granulations, the internal and external use of iodine is beneficial. The potassium or sodium iodide should be given in small doses, and not freely, as in syphilis. Iodine is indicated in the subacute, rebellious, or chronic form of rheumatism, and particularly in nodose rheumatism, which has been observed in young children. The conjoined local use of iodine is here of service. Jules Simon prefers to alternate the iodine with colchicum, prescribing for fifteen days from five to ten drops of the tincture of colchicum and, for the remainder of the month, fifteen centigrams (about two and one-half grains) of potassium iodide. The asthma of juvenile patients is favorably influenced by the same salt. Severe paroxysms of this disease may oc-

cur in very young infants. All pulmonary affections attended by spasmodic attacks, as emphysema, bronchitis, whooping-cough, tracheo-bronchial adenopathy, etc., are benefited by administration of the same remedy. The most tender age is no bar to its employment. Iodine is of service in the obesity of children and endemic goitre. In the latter disease the tincture has been injected with good results. In chronic renal and cardiac diseases (nephritis, chronic endocarditis at the period of compensation) it is also of advantage. Certain tumors, abscesses, and empyemas are due to actinomycosis, and in such cases potassium iodide is the main reliance. The field of usefulness of iodine is large; its contraindications are few. It should not be given internally in pulmonary tuberculosis, especially when acute or febrile. In emaciated and cachectic infants, when the cachexia does not depend upon syphilis, iodine and its compounds should be avoided, and also, according to Comby, in pruriginous affections of the skin. The external use of iodine is a valuable revulsive measure. Potain does not fear the danger of its producing albuminuria, as was observed by Jules Simon in a number of cases.—*Bulletin Medical*.

Mental Symptoms Occurring in Bodily Disease.—According to Dr. Reynolds, mental symptoms occurring in bodily disease may be divided into those slight mental changes in the feelings and emotions not amounting to actual certifiable insanity, and actual insanity. The slight mental states may be roughly subdivided into pleasurable feelings, depressed feelings, conditions of mental dulness, abnormal irritability of temper, and feelings of terror. He concludes that (*British Medical Journal*): 1. It is a comparatively rare occurrence for actual insanity to develop during the course of bodily disease. 2. In general hospitals mental disease most commonly occurs after fevers, poisons, injuries, operations, and heart disease (in about this order of frequency). 3. In the early stages of fevers and after injuries and operations, mania is the commonest form of insanity; but in other conditions depression is more common; but the commonest form is an insanity with marked delusions of persecution (often associated with hallucinations of hearing), such as one sees in phthisis and heart disease, and after typhoid fever. 4. There is no form of insanity connected with special bodily disease, so that it is impossible to diagnose the bodily disease from the mental symptoms present (except the peculiar state of alcoholic paralysis). 5. Insanity occurs with unusual frequency in bodily disease associated with peripheral neuritis, as poisoning by alcohol, carbon bisulphide, and lead; pellagra, typhoid, typhus, scarlet, and rheumatic fevers, influenza, pneumonia, phthisis, syphilis, septicæmia, rheumatism, gout, and diabetes. Is it possible that in these conditions the factor which causes the changes in the peripheral nerves causes also similar changes in the multitudinous internuncial fibres in the brain, and so produces disturbances in the normal cerebral reactions which go to make up a healthy mind? 6. When the cause is not continuous—such as the poisons, the fevers, and the traumata—the mental symptoms in the great majority of cases disappear; in heart disease and phthisis they may disappear and reappear from time to time, but in some cases, such as insanity connected with gouty kidney, they only disappear with death.

The Treatment of Uterine Hemorrhage during the Last Two Months of Pregnancy.—Dr. W. J. Smyly calls attention to the fact that uterine hemorrhage, occurring during the last two months of pregnancy may result from a wound or disease. In the majority of cases it is due to premature separation of the placenta.

Those placental hemorrhages which proceed from the normal site are distinguished as accidental, and those from an abnormal site as unavoidable. All cases in which the placenta dips down below the contraction ring should be considered anatomically as examples of placenta prævia. Clinically, the majority of them cannot be diagnosed as such, and are therefore classed among accidental hemorrhages. The diagnosis of placenta prævia depends upon hemorrhage occurring toward the end of pregnancy or the commencement of labor, and feeling the placenta through the cervix or os uteri. It is difficult to account for the hemorrhages which occur before labor begins. They may possibly be due to a disproportion between the placental site and the placental area. When commencing with labor, they are due to the physiological process by which the ovum is separated from the lower part of the uterus. The lower uterine segment is hemispherical at the commencement of labor, and is occupied by the presenting part of the fœtus through which it directly receives the uterine pressure, and over which it is directly drawn upward, being converted, as the os dilates, into a cylinder equal in circumference to the presenting part of the child. The bag of water is, at the same time, pressed down into the cervical canal, which it dilates, as it does also the external orifice. So long as the membranes remain intact, the ovum is driven down by the uterine contractions, the lower segment being drawn upward at the same time. A separation takes place between the two, and the lower pole of the ovum is cast free from its uterine connections. This separation begins at the os internum and gradually extends upward toward the contraction ring. When the membranes rupture, however, the fœtus only is driven downward, the membranes being drawn upward, with the uterine wall to which they are attached. If the placenta, which is a specially modified portion of the fetal envelopes, should be developed at the lower pole of the ovum, it will be separated with the latter and hemorrhage occurs. More vessels are opened as the detachment extends, but as the detachment may cease with the rupture of the membranes, so may also the bleeding. Smyly sums up the treatment of accidental hemorrhages as follows: 1. When the os is small and labor-pains weak or absent, preserve the membranes intact as long as possible; in external hemorrhage plug the vagina. 2. If labor be well advanced rupture the membranes, and if hemorrhage continue, deliver by the safest method available. 3. For internal concealed hemorrhage, and in some cases of external hemorrhage, if a vital necessity, deliver by accouchement forcé or Porro's method. In all cases the ruling principle should be to proceed with as little force and precipitation as possible.—*British Medical Journal*.

Treatment of Lupus.—Dr. Schutz advises the following treatment of lupus (*The British Medical Journal*): After chloroformization all the friable tissue is scraped away with the sharp spoon; then the floor of the wound and the borders to a distance of one centimetre are scarified. When bleeding has been stopped, the wound is dabbed over several times with a cold saturated alcoholic solution of zinc chloride, to which a little hydrochloric acid has been added. During the ensuing six hours sharp pain is felt which may be mitigated by iced compresses. Before twelve hours have passed, local swelling comes on, more or less pronounced, of the neighboring parts. Boric-acid compresses disperse this œdema in thirty-six hours and cleanse the wound. For four days afterward a dressing of pyrogallic acid (1 in 4) in vaseline is applied thrice daily; then boric-acid compresses, frequently changed, are substituted. After five days of these compresses, pyrogallic acid in vaseline is again used and continued

for four days; then boric compresses are applied again for three days. A final application of pyrogallie acid in vaseline is made for two or three days. Cicatrization is rapidly obtained by iodoform in powder or boracic acid in vaseline. Duration of treatment is from two and one-half to three months. An excellent-looking scar is the result. Recurrence may take place at one or two points. If so, the nodules must be scraped away with the sharp spoon and zinc chloride applied. The author claims that the results of this treatment are more satisfactory than those of any other plan known to him. The treatment is applicable to skin lupus. For mucous membrane in readily accessible situations, such as the gums and the uvula, Schutz recommends applications of a watery solution (twenty to thirty per cent.) of zinc chloride.

Alterations of the Urine in Malaria.—At a recent meeting of the Vienna Medical Society, Dr. von Limbeck related the results of researches which he had made in two cases of malaria. In these cases the elimination of nitrogen was in relation with the elevation of temperature; the proportion of urea and the total quantity of nitrogen were not modified; the elimination of ammonia also was in direct relation to the elevation of temperature; the quantity of urea was augmented, but the relation between the ammonia and the total quantity of nitrogen was normal. During the febrile accession the quantity of phosphates was found diminished; they did not increase until after the access. Freund had also found a retention of phosphates during the febrile stage in some other infectious diseases. The elimination of chlorides, contrary to what occurs in other infectious diseases, is enormously increased during the malarial paroxysms; this fact is so characteristic that the author thinks it may be accorded a real diagnostic value.—*La Semaine Médicale*.

Tumor of the Corpora Quadrigemina.—Drs. Guthrie and Turner report the case of a piano-maker who, three years previous to observation, was affected with earache and slight discharge. Complaining of frontal headache and vertigo he was admitted to the hospital. Examination: Patient much emaciated; semi-conscious; expression dull and listless, though not indicative of pain; some tenderness in the occipital region and in right side of neck; head retracted and turned to right. Raised to a sitting posture he would fall heavily back; placed on his feet he was unable to stand because of inclination backward. Could walk in short steps when strongly supported; gait not ataxic. Paresis of right external rectus; spasm of both internal recti (marked convergent strabismus); pupils moderately dilated; right reacted moderately to accommodation, doubtful to light; reaction to both was doubtful in left; no ptosis; most intense bilateral optic neuritis. Beyond the paresis of the right external rectus there was no paralysis of any part of the muscular system, though there was some tremulousness of the right arm and hand. Some incontinence of urine and constipation. Complete absence of knee-jerk on both sides. Superficial reflexes, cremasteric, abdominal, and plantar, exaggerated. A diagnosis of cerebellar tumor or abscess—probably the latter—was made and the patient trephined with negative results. The patient died a week after the operation. The necropsy revealed slight milkiness of the cortical pia arachnoid with increase of the cerebro-spinal fluid and matting of the membranes over the base; considerable dilatation of both lateral ventricles and excess of the ventricular fluid. A hard, somewhat nodular swelling occupied the position of the quadrigeminal bodies and extended into the left optichthalmus. Microscopical examina-

tion showed the tumor to extend from the junction of the posterior and middle thirds of the left optic thalamus as far back as the posterior border of the testes. It involved the posterior part of the left optic thalamus and merely pressed upon without implicating the right thalamus. It destroyed both the anterior and posterior quadrigeminal bodies, the right being less implicated than the left. It invaded the gray matter around the Sylvian aqueduct, and passed up to and involved the dorso-mesial part of the subthalamie region on the left side only. The tegmentum pontis et cruris was unaffected. The left lateral fillet, in its course to the left testis, was involved. Histologically the tumor was an angio-sarcoma. Attention is called to the two prominent symptoms of tumor of the corpora quadrigemina—unsteady gait and oculo-motor paralysis—and in addition to the fact that vision is not materially altered, except by the condition of the optic neuritis, a constant feature of such cases.—*University Medical Magazine*.

Variolous Immunity of the Fœtus from the Mother.—At a recent meeting of the Paris Academy of Medicine M. Hervieux read the report of the following case by Dr. Annet, a military surgeon: A young woman of twenty-four was revaccinated successfully in the fifth month of her first pregnancy; her child was vaccinated at three and at six months, the latter only being successful. "So far," says Dr. Annet, "nothing is unusual, for we know that immunity transmitted from the mother rarely persists beyond five or six months." But the patient became pregnant again in 1894, four years after, and this second child was inoculated at the second, seventh, and eleventh months; all attempts failed, though the vaccine matter had been used in several other children and always with success. M. Annet expressed the opinion that this immunity could only have been conferred by the blood of the mother. M. Hervieux, in discussing the case, said we do not recognize this transmission of immunity as one of the possibilities. A more acceptable supposition is that the second child was refractory, not from maternal immunity, but by reason of its individual constitution. We see persons who are repeatedly vaccinated with the greatest precautions, with irreproachable vaccine matter, and always unsuccessfully. But suppose they were inoculated ten times without success; nothing enables us to state that the next time would fail also. So, for the child mentioned by Dr. Annet, a fourth vaccination might have succeeded. M. Hervieux might have materially fortified his position, had it been necessary, by a reference to that wonderful storehouse of facts and philosophical deductions, "Original Investigations on the Natural History (Symptoms and Pathology) of Yellow Fever," 1854-1894, by Dr. Joseph Jones, of New Orleans. In his second chapter, on the "Communication of Yellow Fever Through the Mother to the Fœtus in Utero," he has brought together a number of important observations, covering a period of more than a hundred years, bearing upon the transmission of the poison of small-pox through systems "themselves entirely protected from its influence, and demonstrating the existing of the poison in a potential active state, as shown by the excitation of genuine small-pox in the fœtus in the womb of the mother protected by previous inoculation, vaccination, and small-pox." The conclusion is unavoidable that no degree of immunity is conferred upon the fœtus through any variolous or vaccinal experience of the mother, and the lesson of Dr. Annet's case, for the sanitarian and health officer, is to repeat vaccination whenever there is exposure to the small-pox contagion, and often enough to demonstrate insusceptibility.—*Journal of the American Medical Association*.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BRADSHAW LECTURE—THE GENERAL MEDICAL COUNCIL—THE SPECIAL DISCUSSION AT THE MEDICO-CHIRURGICAL SOCIETY—BRITISH MEDICAL ASSOCIATION—CANON WILBERFORCE'S ACCUSATION OF HOSPITALS—ROYAL SOCIETY—LISTER—ACLAND—THE ADJOURNED DEBATE ON LATENCY IN DISEASE AND IN GERMS—THE PROPOSED NEW HOSPITAL—DR. ANDERSON'S CASE—THE ASYLUM BOARD.

LONDON, December 6, 1895.

YESTERDAY the Bradshaw lecture was delivered at the Royal College of Surgeons by Mr. Macnamara. He took as his subject infective and tubercular osteitis as causes of arthritis in childhood. He advocated early surgical treatment and particularly the use of the trephine.

The General Medical Council which was left sitting when I wrote last week continued its discussions over the following Monday. The application of the Dublin Apothecaries' Hall to the Council, to appoint examiners in surgery under the act, was after long discussion refused, and it is understood that the Hall will now apply to the Privy Council for assistance. What that august body may do it is not possible to foresee. There is a pretty general feeling that the Hall has been rather scurvily treated. Not that its disappearance from the too long list of qualifying bodies would be a calamity. On the contrary, it could be well spared, as indeed several others; but there is a proverb, "fair play is a jewel," and to get rid of a legally constituted corporation by a side-wind can scarcely be called fair play. Besides it is quite possible the Privy Council may determine in favor of the Hall, and then our General Council will be seen to have acted from prejudice—though, to be sure, that will be nothing new.

There was the usual tedious talk on the perennial education question, and the diplomas issued in sanitary science were duly considered. These latter certificates have been sufficiently bepraised, though it is not so easy to see why their multiplicity is beneficial. We have fifteen different diplomas in public health, all of which have grown up under the fostering care of the Council and put money in the coffers of the corporations.

One resolution of the Council is likely to give lively satisfaction to many practitioners. It was determined to put in force the act against the false assumption of medical titles. This in the fifty-first session of the Council! Surely it was time for this body to exercise the power conferred upon it by Parliament and to do its duty in protecting the public and the profession. The penal clause has been left dormant through fifty sessions.

The first evening of the second fixed debate at the Medico-Chirurgical Society seems to have afforded satisfaction. The subject selected was the possibilities as to the latency of parasitic germs or specific poisons in animal tissues. This was introduced by the president, Mr. Hutchinson, who restricted the term latency to periods when no vital activity of the organisms was going on, but did not include the period of incubation, and *a fortiori* excluded that of prodromal symptoms. He illustrated his meaning by the example of a field in which poppy-seed had remained quiescent for eight years and then grown, and asked what evidence there is that micro-organisms can exist in such a quiescent state, and if so what are the limits of such latency and what the conditions which govern or determine it? Latency has a bearing on infection,

as it is easy to perceive that what looks like a fresh infection might be due to the termination of the latent period. We may suppose that various changes in the tissues may excite the latent germs into activity, and such an event may account for cases which have been supposed to be due to accidental infection in vaccination. Is it possible that latent germs may be transmitted from parent to offspring? Such a hypothesis would explain many things. Tuberculosis, erysipelas, hydrophobia, leprosy, and other diseases afford abundant material for speculations of this kind. Recurrence of lupus after many years of freedom may possibly be due to latent germs, and not to reinfection.

Dr. Washbourn addressed himself to the bacteriological aspect of these problems. The life history of bacteria in reference to latency, as he remarked, offers interesting points. The growth of bacteria in broth offers an analogy with the incubation of specific diseases. In favorable conditions they grow at once and soon reach a maximum. In unfavorable conditions the growth is deferred and resistant forms appear. Spores are examples, but even sporeless bacteria may produce resistant forms, e.g., pneumo-coccus. Latent bacteria may then exist in the body in such a phase of development, and Dr. Washbourn thinks some of the clubbed shapes assumed by the bacillus diphtheriæ represent such resistant forms. In animals immunized to diphtheria (and tetanus) the antitoxins in the body antagonize the toxins but do not kill the bacteria, and this explains why the bacilli may remain in the throat without producing disease. The body is poison-proof but not sufficiently bactericidal. In septic diseases there is sometimes increase of bactericidal properties without a corresponding increase in antitoxic effects. Other organisms afford examples of latency. Pneumococci, streptococci, gonococci, and tubercle bacilli have been found on mucous membranes without setting up disease, and other examples have been recorded, some in which the latency has extended over long periods.

Dr. J. Kingston Fowler then stated the evidence for the belief that it is possible for the specific poison of tuberculosis to remain latent in animal tissues. It may be argued: (1) That the disease, having been arrested, may, after a period of quiescence, again become active, reinfection from within taking place. (2) That tuberculosis may be produced by the inoculation of an animal with material taken post mortem from an old tuberculous lesion. (3) That the virus may pass directly from parent to offspring and set up the disease in the child. A number of facts bearing on these propositions were stated, being drawn for the most part from cases of pulmonary tuberculosis. The evidence for a long period of latency in a child infected by the mother is far from conclusive, but Dr. Fowler seems to think it will in future be found more common than is supposed. But he by no means indorses the opinion of Baumgarten that this is a very common occurrence, nor that the latency may pass over a generation and the virus become active in the grandchild. Latency is not arrest in which the virus may be dead.

The debate was adjourned until next week.

Carlisle has come to the rescue of the British Medical Association, and the invitation will no doubt be gladly accepted. So next year the meeting is likely to be in that interesting town.

Canon Wilberforce has been ranting in the *Times* on vivisection and exposed himself to ridicule and worse. Professing to supply proof that our hospitals are used for shocking experiments on patients, he has been given the "lie direct." What a pity that a church dignitary should justly incur such a sentence!

The Royal Society had its annual meeting last Saturday. Sir Joseph Lister was elected president.

Sir H. Acland received a very handsome testimonial last Wednesday, a sum of £3,000, which will be employed by the Acland Nursing Institute. His bust is to be placed in the museum of the Oxford University where he has worked so long.

LONDON, December 13, 1895.

THE debate on Latency was resumed on Tuesday, though in a somewhat languid manner, the original papers having pretty well exhausted the subject.

Drs. Squire and Fowler drew a distinction between latency of the germ and latency of the disease which was not observed by all speakers. Dr. Sibley looked upon latency as a sort of hibernation of the germs. He had found tubercle bacilli would not grow in snakes at their ordinary temperature, but when the infected creatures were placed in an incubator tuberculosis supervened and on removing them the process became stationery. Perhaps it would do so in hibernating animals.

Dr. Abraham spoke of leprosy—but he admitted we do not know of any definite period of incubation and cannot clinically determine the date of entry of the microbe. It would seem, therefore, we must look to gentlemen practising where the disease is rife, for the opportunities of seeing it in this country are happily few and the opinions of English practitioners of little interest. Mr. Ernest Lane spoke of the way in which latency may occur in syphilis. This was also alluded to by Mr. Spencer Watson, who said glandular enlargements were to be found in quiescent periods and showed the need of treatment.

Dr. Lazarus-Barlow thought the question whether a given microbe remained latent depended on its environment, and instanced the pébrine of silkworm disease and other examples of this. Sir William Broadbent thought the introductory papers left little or no room for criticism. He remarked that latency was foreseen clinically before it was proved experimentally, and the experimental explanation was of great interest to clinical observers.

Dr. Manson said the causes of latency were various even for the same microbe. Malarial germs were not killed by quinine but merely rendered latent, and these germs may also be made latent by improved health in the host, and this was true in other cases, some of which he instanced. Dr. Ogilvie spoke of the difference between latency and immunity, and criticised the president's distinction between true and apparent latency in syphilis. He thought the duration had been unduly extended by crediting syphilis with non-specific diseases which occurred in infected subjects. The so-called syphilitic nervous diseases he found did not differ from other forms. Any irritation might bring out manifestations of latent taint. The president replied that in real latency there is complete quiescence. If the germ be in any degree active there is only apparent latency. If a man passed through the secondary stage of syphilis without any manifestation but then had tertiary symptoms, the latency was only apparent, for the poison had been at work, and it was possible that very careful investigation might have found some indication of this, e.g., a slight rise of temperature.

The proposal to build a new hospital for South London is exciting some serious opposition, and this is natural enough when both Guy's and St. Thomas's have empty wards. Would it not be better to find funds to fill them than to spend money in brick and mortar and the other costs that would accrue?

Dr. Anderson's case is being well managed by the Civil Rights Defence Association and it is hoped that it may be carried to the House of Lords or that he may be compensated by Parliament.

The position of the Asylums Board is most unsatisfactory. Their hospitals are crowded and they cannot

receive all the cases, so complaints are numerous, but the difficulty of obtaining sites continues and the cost is ever increasing. No doubt many now avail themselves of these hospitals who could very well be isolated and treated at home. But the profession cried out for isolation, and is reaping the reward of its disinterestedness in decreased incomes.

OUR PARIS LETTER.

THE PRACTICE OF MEDICINE IN PARIS—EFFORTS TO EXCLUDE FOREIGN DOCTORS AND TO DISCOURAGE STUDENTS FROM COMING TO FRANCE—STRINGENT NEW LAWS—RED TAPE—AN OVERCROWDED PROFESSION—REGISTRATION ACT, ETC.

PARIS, December 15.

THE increase of foreign doctors practising in Paris or desiring to do so has been so great during the last few years, that steps have been taken by the Chamber of Deputies and the Senate, doubtless at the instigation of the Academy of Medicine, prompted in turn by the profession at large, to put a check upon this steady influx of physicians from abroad, to which the United States has contributed its share.

During the second Empire matters became very facile in this respect, either because the Emperor Napoleon III. did not consider them of sufficient importance to the State to merit any serious action, or because he thought it best that they should remain as they were and thus keep the foreign relations of France upon a more amicable basis. This applied chiefly to those who were already doctors of other than French schools and only wanted permission to practise in Paris. This brought younger men to the capital, men who were just beginning their studies and many of whom went through the full four or five years' course, passed all the examinations, and took the degree of Doctor of Medicine of the Faculty of Paris, which was then, as it is now, considered by all Frenchmen, and many other nationalities as well, to be the first in the world. It is not at all improbable that the Minister of the Interior, by whom Napoleon was greatly influenced, also thought that the foreign doctors and students, who then began to come to Paris by thousands, would be a good thing for trade, and make taxes easier to be collected and levied; for example, that upon practitioners for the right to exercise their profession, over and above the ordinary taxes. This tax or patent has been increased within a year or two, since the new law regulating the practice of medicine came into force. Thus it was that everything went on with loose reins for many years; it only being necessary very often to use a little influence with the American Minister, who would apply through the Minister of Foreign Affairs to the Minister of Public Instruction or to the latter directly, for permission to practise medicine in Paris—permission rarely if ever refused in those days and under those circumstances, for the applicant was of course always a distinguished practitioner or had done original work, or was prominent and influential at home, either socially or politically, etc. Sometimes he had all these desiderata. Permission could be given to practise anywhere on French territory or only in the department of the Seine, of which Paris is the principal city; in many instances it was accorded without thesis or examination of any kind, in others a thesis or clinical examination was considered essential, the examination being conducted in one of the larger hospitals, where a medical and then a surgical case were given by the board of examiners to the candidate, who, being a practitioner of some experience at least, found little or no difficulty in making a tolerably correct diagnosis and outlining a treatment. In 1888 the first signs

of a serious reaction began to manifest themselves, and as late as 1890 Professor Brouardel, the Dean of the Faculty of Medicine, informed us that the number of applications from foreign doctors to practise medicine in Paris averaged two hundred and fifty a year. It was not long after this that he published statistics showing that when the number of practising physicians in France was more than one for every twelve hundred inhabitants it was impossible for the physician to live, and that ratio has been attained; moreover, France has become protectionist. Projects of law were now sent to the Chamber of Deputies, and after many preliminaries, committee meetings, and revisions, the law of 1892 was adopted and passed. The law of the year XI. that came down to us from Napoleon I. has been abolished and the power of granting permission to foreigners to practise medicine in Paris has been forever taken away from the Government. The obnoxious article ran thus: "In virtue of article 4 of the law of the 19th Ventôse, 11th year, the government may accord to a foreign doctor the authorization to practise in France. This authorization may be conferred for the whole of France, or only for a province, or even for a city; it is always revocable." Such was the qualification given sometimes to those quite unqualified for Paris practice, and it was rarely if ever revoked.

The second part of the law has been retained in a more modified and much more stringent sense. It was as follows: "Foreign doctors desiring to acquire the French diploma may be dispensed in certain cases with passing a part of the examinations for the doctorate." And we have seen how they were often dispensed with, in the foregoing portion of this letter. To the old law is added that "in no case shall the dispensation exceed three examinations." The examinations are scheduled as five, but they in reality amount to ten, as several of them are divided into two or three parts, which must be passed at intervals of several weeks and separately, as if they were not parts of a whole; after which a thesis must be written and publicly sustained. There is a tendency to do away with any dispensation whatever, and a decree has just been made public by the conseil supérieur, that no foreign students will in future be permitted to study in Paris, but they may receive permission very exceptionally to study in a school of medicine in one of the provinces. The pressure is so great against admitting foreigners to the study and practice of medicine in Paris, that at no very distant day no one will be allowed to practise medicine in France who is not a born or naturalized Frenchman. That is what in our opinion we are coming to and that is what actually exists in the legal profession. The difficulties of complying with the already existing regulations are great enough, to say nothing of applications to the minister or ambassador of the country to which the postulant belongs, and the immense amount of red tape to be gone through with, even if he gets the Sorbonne to accept his college degree and other evidences of preliminary education as equivalent to theirs.

The matter is finally submitted to the Academy of Medicine, which decides under exactly what legal circumstances the reception, if accorded, shall take place. At any rate the applicant is sure of eighteen months' hard work at least and large expenses for back inscriptions—library, examinations, etc., if he already be a doctor in medicine of standing and from a first-class foreign medical school. If a student only, he may count upon from four to five years, if allowed to enter a French school of medicine at all, of which there are about half a dozen in different cities of France and which form parts of one composite whole, the University of France. If the examinations are successfully passed—and they are very searching—and all the other requirements strictly fulfilled, the Fac-

ulty of Medicine then requests the government to issue the diploma, which is done by the Minister of Public Instruction. He, the Director of Superior Instruction, and the vice-rector of the Academy, are the only signers except the candidate himself.

But few of the old foreign doctors who received permission in Napoleon III.'s time to practise, are still living. The three oldest American physicians now practising in Paris are mentioned in chronological order: Dr. R. R. Good, Dr. Halsted Boyland, and Dr. A. S. Clarke. Dr. Good and Dr. Halsted Boyland have been identified with Paris since 1870, when both took part on the surgical staff of the French Army in the last Franco-German war. Dr. Clarke is inscribed on the official lists since 1874. All three gentlemen are regular graduates of the University of France. Dr. Good is the consulting physician, Dr. Halsted Boyland gives more especial attention to internal medicine and diseases of the nervous system. Dr. Clarke is the leading general practitioner and a brilliant surgeon.

It goes without saying that all the examinations are conducted in French, a thorough knowledge of which is absolutely necessary. Every medical diploma must be registered at the Prefecture of Police and with the registrar at the Palace of Justice, otherwise the holder will be prosecuted for the illegal practice of medicine.

The question, whether the French are acting wisely in thus trying to exclude, and as a matter of fact excluding, all foreigners from the practice of a liberal profession in their territory, is one belonging rather to political economy than to legal medicine, and we leave it there.

OUR CANADIAN LETTER.

(From our Special Correspondent.)

SIR WILLIAM HINGSTON HONORED—INTER-PROVINCIAL REGISTRATION—NEW PRINCIPAL FOR MCGILL COLLEGE—THE QUESTION OF LODGE PRACTICE IN CANADA—THE DISPENSARY EVIL—SPURIOUS MEDICAL JOURNALISM.

ONE who has long been regarded as one of the most distinguished members of the medical profession in Canada, has recently had conferred upon him by Her Majesty, Queen Victoria, the honor of knighthood. The new medical knight is Sir William Hingston, the well-known Montreal surgeon. A banquet has been tendered him by the medical profession and a perfect shower of congratulations has attested the popularity of the well-merited distinction. Sir William Hingston is the first medical man in Canada who has ever received the honor of knighthood solely on his merits as a surgeon. In fact it is only in the arena of professional work that he seems to achieve success, for but a few days ago he suffered defeat in an election for the House of Commons, although every one concedes to him a first place in the ranks of the profession he has long and faithfully adorned. To such men are often denied the honors arising from political warfare, but it is satisfactory to note that Her Majesty has in this instance honored the rolls of knighthood by inscribing thereon the name of a Canadian surgeon who holds such a high place in the esteem of the profession.

Inter-provincial registration has long been a vexed question with the profession in Canada. It may seem very peculiar to our American friends to know that in each of the eight provinces of the Canadian Dominion there is a separate and distinct medical council, and that no matter what the qualifications of a medical man may be, he is not permitted to remove to another province and practise his profession without first passing the prescribed examinations legalized by

the medical council of that province. Recently, through the efforts of the Canadian Medical Association, some advancement has been made and there is ground for hope that before long we shall have in Canada a uniform standard of matriculation, a uniform standard of medical education, and a uniform method of examination for the whole dominion. In order to secure this oft-desired consummation each provincial council will probably be compelled to submit to some modifications; for example, in Ontario, where a five-years' course of study with attendance on lectures for six months in each year is demanded, a change may be made to a four-years' course of nine months each. The committee appointed by the Canadian Medical Association is fortunately a representative one and is composed of medical men from the different provinces who understand the importance of the matter committed to their care, and from their efforts we are hopeful of an early delivery from the anomalous condition in which medical registration is at present. While the medical councils in the different provinces provide the very best protection possible to the profession, the proposed inter-provincial registration will not only permit the holders of dominion licenses to practise in any Canadian province, but will also enable them to register with the British Medical Council and enjoy all the privileges accorded to members of that body.

McGill University, Montreal, has lately welcomed a new principal in the person of Dr. Peterson, who comes to Canada from Dundee, Scotland, where his brilliant career as a university administrator won for him such distinction as to bring his name prominently before the governors of McGill when a successor to the late Sir William Dawson became necessary. The good work achieved by the latter will long be remembered, and if the new principal proves as successful in directing and giving special tone to the education of the English-speaking inhabitants in the Province of Quebec, McGill may well be proud of the selection made. The excellent work being done in the biological and pathological departments of McGill amply justifies the princely beneficence which has so richly endowed and supplied the men and the material to achieve such pleasing and satisfactory results.

The question of lodge practice has been much discussed in medical associations in Canada during the last few years, and the product of this discussion has been a growing feeling that all contract practice is derogatory to the interests of both the profession and the public. The medical men of the city of London, Ontario, have recently come to an agreement that, commencing with January, 1896, all lodge and contract practice shall be discontinued, and through the exertions of a live medical association a document has been drawn pledging each practitioner to decline every offer of such work. The feeling is that if this effort to stamp out what has long been regarded as a most obnoxious evil is successful in London, it will not be long until lodge practice, now admitted after patient experience to be an offspring of quackery, shall be abandoned in Canada.

Another evil, which it is admitted has a marked tendency to pauperize the medical profession, is the dispensary system. In several of our larger cities where medical colleges exist and where clinical material has to be provided, a great injustice is done to the general profession by the existence of these dispensaries. The students' fees in most cases pay the professor very fairly for his lectures, and in the great desire to secure material no questions are asked, so that the public gradually find out that they may thus avoid consulting the medical man, who is forced to look on and see all the interesting cases drift to the dispensary. The public are found quite willing to

assist in this work of commercialization of the profession, and are indeed glad to see the same methods, such as bargain counters, etc., which they have found so convenient in dry-goods and groceries gradually being not only established but well patronized in regard to their medical requirements. The cities of Toronto and Montreal have become quite notorious in Canada for thus propagating and encouraging the dispensary evil, and all in the name of what is so absurdly designated as charity.

Medical journalism in Canada is to be congratulated on the recent disappearance of a journal which, although issued once a month and sent to every practitioner gratis, was, nevertheless, a purely advertising journal. The members of the profession have in many instances refused to be parties to what is now shown to have been a most questionable undertaking. The scheme was to publish two editions of a medical journal, one on superior paper and with better finish than the other. The former was sent only to the advertiser, with the assurance that a copy of that journal went into the hands of every practitioner in Canada, whereas the edition which really went to the members of the profession was an inferior cheap one, filled three-fourths part with advertisements. The grocer, the butcher, the baker, and even the candlestick-maker each had his advertisement sandwiched in with the reading matter, and the whole was sent out as a model of Canadian medical journalism. Fortunately the profession saw through the dodge, and even the much-fooled advertisers are seeing the deception practised upon them. It is safe to predict that these spurious attempts to secure the sympathy of the profession with bogus journalism will only more firmly establish those journals which exist on reputable foundations.

OUR PHILADELPHIA LETTER.

PHILADELPHIA AND WEEKLY JOURNALISM—DR. GEO. M. GOULD—AMERICAN PHYSIOLOGICAL SOCIETY—SOCIETY OF NATURALISTS—PSYCHOLOGICAL ASSOCIATION—UNIVERSITY OF PENNSYLVANIA—ANTITOXIN—FUMIGATION OF CAR CUSHIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The medical profession of our easy-going city was a short time ago disturbed by the rumor that its most esteemed medical journal was about to be transferred to new and more active surroundings, and with the first of the year the *Medical News* will be a New York publication. "Business reasons" constitute the motive given for the change. Philadelphia has been the mother of much of which the American medical profession may be proud, and this present loss is felt most keenly—not that we shall be left without medical journals, but of these it were charitable to be silent. We have still with us the *American Journal of the Medical Sciences*, which yet holds a dignified place in current medical literature. There has naturally been some talk of the publication of a new weekly, but thus far nothing has materialized.

The migration of the *News* carries with it the retirement of its editor for the past five years, of whom the least that can be said is that he has devoted his best energies to the advancement of the medical profession and the maintenance of a high standard of professional ethics. In these efforts he has partly succeeded. That he has not more largely done so is principally due to the spirit and tendencies of the times and not to a want of zeal or activity on his part. He has been particularly severe in his denunciation of sectarianism, quackery, and charlatanism of all kinds, both without and within the profession, and we can imagine some places where his deposition will be hailed with delight.

Ordinarily dull at this holiday season, Philadelphia is this year enlivened by the simultaneous meeting of seven learned bodies. The Geological Society of America, the American Society of Naturalists, the American Morphological Society, and the American Folklore Society began their sessions on Thursday, the 26th instant, and the American Physiological Society, the Association of American Anatomists, and the American Psychological Association theirs on Friday, the 27th instant. Most of the meetings were held in the halls of the University of Pennsylvania, and the sessions were interspersed with the usual receptions and dinners.

The Society of Naturalists agreed to oppose any action looking to the abolition of vivisection, and the following were appointed members of a committee having that end in view: Dr. William Patton, of Dartmouth, Dr. W. T. Sedgwick, of Boston, and Dr. Charles W. Stiles, of Washington.

Among the papers read before the Psychological Association was one by Dr. George S. Fullerton, of the University of Pennsylvania, entitled "Psychology and Physiology," in which an attempt was made to draw the line in experimental researches which the investigator in either field should not cross. From this proposition, however, there was some dissent. Dr. Livingston Farrand read a "Description of a Series of Physical and Mental Tests on the Students of Columbia College." Mr. Oliver Cornman detailed an "Experimental Investigation of the Processes of Ideation." Prof. J. McKen Cattell spoke in defence of experimental psychology. Papers were also read by Dr. Arthur MacDonald on "Psycho-neural Data," by Prof. Charles A. Strong on "Consciousness and Time," and by Brother Chrysostom on "Some Conditions of Will-Development."

Ex-Mayor Edwin H. Fitler, who was for a time President of the Board of Trustees of Jefferson Medical College, has made a Christmas gift of \$10,000 to the University of Pennsylvania "for a special purpose," with the provision that the Trustees of the University raise the remainder of the sum required.

Although the utility of antitoxin in the treatment of diphtheria seems practically established and almost universally admitted, the remedy is being used in our Municipal Hospital in only a half-hearted way and the results are correspondingly discouraging. Few institutions afford a better field for the employ of the now no longer new or untried remedy, the use of which elsewhere has done so much to reduce the mortality of diphtheria.

During our recent street-car strike and tie-up, driving was for a number of reasons safer for individuals who were fortunate enough to be possessed of horse and carriage, while those who were not thus provided and who owned bicycles found much convenience and comfort in these vehicles, which are rapidly growing in favor with medical men and women, and not only the younger element but the more mature as well.

A correspondent of the Board of Health has suggested the fumigation of the cushions of the street-cars that were used during the strike as beds for imported conductors and motormen, but the communication was ignored as unworthy of serious consideration. Systematic disinfection of street-cars and railway-cars would probably be a means of averting much disease and saving many lives.

Dr. Albert E. Protsman, a young physician, was killed by a trolley-car in dismounting from his carriage.

The Charity Hospital of New Orleans has recently had added to it an amphitheatre, known as the "A. B. Myles amphitheatre." It was opened with elaborate ceremonies on October 16th.

THE REASON WHY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Not long since I chanced to overhear a part of a conversation between two gentlemen, in regard to a premature birth which had happened in the family of an acquaintance. In brief, the occurrence took place two months ahead of schedule time. In commenting on this, the narrator expressed the belief that, being a "seven-months" child, it stood a better chance of living and thriving than it would had it spent another month in utero. This appeared to me so evidently irrational, that I classed it, without much further thought, with the many strange beliefs current among the laity, until I happened on the following explanation:¹

"Now, that a childe borne in the seuenth moneth may lue, both Astrologers and Phisicians doe affirme,² but in the 8. they deny it; and these are their reasons: The Astrologers hold, that the childe in the mother's wombe, is successively gouerned every moneth, by the seven Planets, beginning at Saturne: after which reckoning, he returning to his rule the 8. moneth, by his dreery influence, infortunateth any birth that shall then casually befall: whereas his aucceeder Iupeter, by a better disposition worketh a more beneficiall effect.

"The Phisicians deliuer,³ that in the seuenth moneth, the childe, by course of nature, turneth it self in the mother's belly; wherefore, at that time, it is readier (as halfe loosed) to take issue by any outward chance. Mary, in the eighth, when it beginneth to settle againe, and as yet retayneth some weaknes of the former sturring, it requireth a more forcible occasion, & that induceth a slaughtering violence. Or if these coniecturall reasons suffice not to warrant a probability of the truth, Plynies⁴ authority in a stranger case, shall presse them farther: for hee writeth, that a woman brought a bed of one childe in the seuenth moneth, in the moneth following, was also deliuered of twines."

S. AUSTIN DAVIS, M.D.

BAYONNE, N. J.

IN REPLY TO THE STATE COMMISSIONER IN LUNACY.

TO THE EDITOR OF THE MEDICAL RECORD.

IN a previous issue of the RECORD appears a letter from Dr. Carlos F. MacDonald defending his action in going upon the witness-stand as an expert witness, in which he attempts to justify himself by partially quoting the law of this State, and is careful to omit the reference to his own duty in the matter. As this is the gist of your editorial, I may be pardoned for quoting Section 33, Chapter 446, of the Revised Statutes of New York, 1889, and have italicized the words which he does not deem it worth while to include in his explanation.

"When any person confined under the indictments of arson, murder, or attempt to murder, or highway robbery, or who has been acquitted thereof on the ground of insanity, and has been committed to some State lunatic hospital, . . . shall be restored to his right mind, *it shall be the duty of the superintendent of such asylum to give notice thereof to the State Commissioner of Lunacy, who shall thereupon inquire into the truth of the fact, and if the same shall be proved to his satisfaction he shall issue certificate, dated under his official hand and seal, to a Justice of the Supreme Court of the district in which such asylum is situated, who shall thereupon and upon such other facts as may be*

¹ Carew's "Survey of Cornwall," 1769.

² Gellius, li., cap. 16, Schonerus.

³ Leninus Lemnius ocul. nat. miraculis.

⁴ Lib. 7, cap. 11.

proven before him, determine whether it is safe, legal, and right that such party in confinement as aforesaid, shall be discharged."

Neither the criminal code nor the amendment of 1890 relieves the medical commissioner from responsibility, because the duties of the old office are shifted upon the shoulders of the commission as a whole, for as a member of that commission his duty is clear.

Very truly yours,

ALLAN McLANE HAMILTON, M.D.

NEW YORK, December 17, 1895.

ASPHYXIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I was much interested in the carefully prepared article, "A Contribution to the Study of the Nature, etc., of Suspended Animation in the New-born," by Dr. Bissell, in the MEDICAL RECORD of November 30, 1895.

He treated cases of asphyxia by inversion, and elaborated a theory, when the condition of inversion, by causing the expulsion of mucus and blood from the air-passages, would seem a palpable reason for his success in three cases.

It must be admitted that the ultimate cause of death from asphyxia in the new-born is a lack of oxygen, due either to obstruction in the air-passages, or to blood too rich in venous elements for passage through the minute and hitherto almost dormant capillaries in the lungs.

Hence it would seem to be a serious omission of obstetric writers when they fail to direct that the new-born should always be laid upon the right side to assist in the closure of the foramen ovale.

I would submit that Dr. Bissell's first case was symptomatic of an open foramen, and the child would have inevitably died if left on its back.

Apropos of inversion, Dr. Hunter McGuire lately made the suggestion in my presence to try anæsthesia with inversion with the hope of avoiding tracheotomy for foreign bodies.

Relaxation, gravitation, and I would add succussion, with pressure below the diaphragm and over the lower ribs, perhaps conjoined with the use of apomorphine, would seem hopeful. For quite often after the patient is anæsthetized and the incision is completed he coughs and dislodges the foreign body.

Here irritation and atmospheric pressure come into play, but without the relaxing effect of the anæsthetic the body might be retained by the same spasmodic contraction which had hitherto prevented its being coughed up.

Chloroform in these cases has several advantages over ether. When practised early and in cases of smooth substances, this procedure is most hopeful.

THOS. R. EVANS, M.D.

MT. CARBON, W. VA.

THE BACTERIOLOGICAL DIAGNOSIS OF DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue for November 23, 1895, Dr. E. V. Brendon cites two instances which undoubtedly justify the unfavorable criticism he makes respecting the methods employed by the New York Board of Health, in its superintendence of cases of diphtheria; and he closes with an expression of scepticism in regard to the reliability of bacteriological diagnosis. Now, in view of the attack thus made by him (and his medical neighbors) on this method of diagnosis; and since, on several occasions, I have expressed my satisfaction with the work done by the bacteriological department of the Board of Health of the city of Boston, having

in every instance received an unerring diagnosis (as proven by subsequent events) expressed in a straightforward manner without the slightest evidence of an attempt at equivocation, I feel it my duty to contribute the little testimony in my possession on behalf of the reliability of the bacteriological diagnosis. I trust nothing will occur to do away with a custom upon which I have learned to lean, as upon a good substantial support, in those times of perplexity which must come to all concerned in the diagnosis of these cases. I do not know Dr. H. C. Ernst personally, but I have long wanted to express my admiration for the faithfulness and efficiency of his service, and I embrace this opportunity to do so; and in doing it I voice the sentiments of all the physicians with whom I have conversed upon the subject. Yours truly,

L. N. DAMON, M.D.

DORCHESTER, MASS.

THE MORPHINE HABIT AND UNTRUTHFULNESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In many parts of the country courts look with distrust upon the so-called "expert testimony" of physicians. I cannot but think opinions like that expressed by Dr. Walker in your issue of November 16th entitled "Some Remarks on the Morphine Habit," are largely responsible therefor. I should not like such an article to go out as the views of the profession. Certainly he has grossly exaggerated the moral perversion of morphine users. Morphine, like alcohol, when used greatly in excess, may, and unfortunately does, make physical and mental wrecks of its victims. Dr. Walker plainly states without qualification, "I would not believe a man addicted to the use of morphine on oath." A man who has used morphine until his whole mental and moral attributes were wrecked, I presume would lie, just as he might do any other depraved thing, but that the moderate use of morphine overwhelms the "truth centre" of a man is to me an absurdity. I think most medical men can recall to mind some one at least who has used morphine for a long time who in every other respect is a gentleman. At what time would the doctor consider a morphine user unreliable? Not the first day or the first week surely. Would he consider the physician who used half a grain each morning that meanest of all mean things, a liar?

What quantity shall a man use daily before his testimony shall be rejected by a court of justice? The fathers used to state that a confirmed opium-user would stoop to any deception when deprived of his drug to obtain his usual supply—a greatly different position from Dr. Walker's. To repeat, I believe that it is just such articles as Dr. Walker's that have made the opinions of the medical profession of but little weight in the courts. I hope you will allow other physicians to give expression to their opinions in your valuable journal. I believe the subject is important enough to justify it. At any rate I want to enter my protest against any such views. H.

The Curative Treatment of Habitual Drunkards is likely to be taken up by the Government in Austria. It is proposed to establish retreats, where inmates shall be received for two years. They may enter of their own accord or be placed there under compulsion. If under compulsion a legal trial must be previously held. The period of retention may be curtailed to one year, the patient being released on a system resembling that of ticket-of-leave. If a patient is shown to be incurable he may be retained for life.

New Instruments.

A NEW ANÆSTHETIC HOLDER.

By DICKSON L. MOORE, M.D.,
COLUMBUS, OHIO.

ACCOMPANYING is a diagram of an arrangement I have devised for holding the ether bottle or can during an operation, which will perhaps be of interest to anæsthetizers.

It may be attached to any operating-table by the side of the anæsthetizer, and serves to keep the anæsthetic out of harm's way from any movements of the patient.

The horizontal bar may be lengthened at will from *B* and affords a convenient place for hanging face towels. The ring *D* is made in two sizes (attachable at *C*), one for an ether bottle or can and one smaller for a chloroform bottle. A muslin stocking *E* is sewed to a wire ring, which, being slightly larger than the ring *D*, is thus prevented from being pushed through.

It has been made for me by Mr. Autenrieth, of Cincinnati.

AN IMPROVEMENT OF WRIGHT'S SNARE.¹

By E. G. BOYD, M.D.,
LEADVILLE, COL.

THE improvement consists of a barbed needle, extending from spring catch of snare to within one-quarter of an inch of the end of cannula.

The needle is attached to snare by one round and

one square loop, which slide along cannula and main body of snare respectively.

Base of needle bar is graduated from before backward for one and one-half inches, that the operator may know the extent of its introduction, and it is provided with a push-button.

On using the instrument, it is well to bend the wire loop upward to a right angle to cannula, retract it for introduction, and when the stylet is again pushed for-

¹ Read before the Colorado State Medical Society.

ward the loop will be at an angle of about forty-five degrees from the end of cannula.

In this way the growth may be seized well at its base and the loop escape engaging the needle, a complication to be guarded against.

I have found this instrument to be of special service in the removal of turbinal varix and other forms of posterior hypertrophy, in which cases I use it as a transfixion needle.

I wish to thank Messrs. George Tiemann & Co., of New York, not for carefully following my directions, but for so modifying them as to give me a neater and more efficient instrument.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 28, 1895:

	Cases.	Deaths.
Tuberculosis.....	90	109
Typhoid fever.....	19	8
Scarlet fever.....	124	10
Cerebro-spinal meningitis.....	3	3
Measles.....	253	18
Diphtheria.....	265	36
Small-pox.....	3	0

The Value of a Human Life.—Previous to the adoption of the present Constitution of New York State the maximum value of a human life had been placed at \$5,000, and no larger sum than this could be collected by the heirs in case a person was killed through the negligence of some person or corporation. The new Constitution, Article 1, Section 18, provides that the amount recoverable for the loss of life shall not be subject to any statutory limitation. The first case to take advantage of this change is that of a Brooklyn man, who brought action against a trolley company to recover damages for injuries which caused the death of his wife. The jury awarded him the sum of \$7,500.

The Chicago Diphtheria Emergency Corps.—The Health Department of Chicago has organized an emergency corps, for the purpose of fighting the spread of diphtheria. The corps consists of fifteen physicians, with a chief, and the plan is to treat the disease as an epidemic and try and stamp it out. All the physicians are required to use the antitoxin treatment, as well as to do intubation and tracheotomy.

Diphtheria is unusually prevalent in London.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

A HANDBOOK OF OBSTETRIC NURSING: For Nurses, Students, and Mothers. By Dr. Anna M. Fullerton. Fourth Revised Edition. Illustrated. 12mo, 253 pages. Price, \$1.00. Published by P. Blakiston, Son & Co., Philadelphia, Pa.

AN ATLAS OF OPHTHALMOSCOPY. With an Introduction to the Use of the Ophthalmoscope. By Dr. O. Haab. Translated and Edited by Dr. Ernest Clarke. Illustrated. 12mo. Price, \$3.50. Published by William Wood & Company, New York.

THYREOANTITOXIN. THE ACTIVE PRINCIPLE OF THE THYROID GLAND.¹

By SIGMUND FRÄNKEL, M.D.,
VIENNA.

AMONG the many therapeutic experiments of recent years one is especially noticeable, that, namely, which has to do with the treatment of various diseases by parts of the animal body or by extracts derived therefrom. We have been accustomed to give exact quantities of known chemical bodies, having known physiological properties, and we have been able to determine the effects of them upon the human body. Now, however, we find a number of remedies of which we do not know the active principles, or how many active principles they contain; we only know that in many diseases without common pathological basis we are able to obtain very favorable results. There is here a very attractive problem to be solved, namely, whether these substances contain any chemically defined bodies which produce the physiological and therapeutical effects noted. English and American physicians have used with success, besides the thyroid gland, the supra-renal capsules, the pancreas, the pituitary gland, the kidneys, the testicles, and bone marrow.

Although many investigators have experimented in order to determine the physiological action of the thyroid gland, no one has yet discovered its active principle. Many have thought that it is either a ferment, an enzyme, a globulin, or an albuminoid substance, but no one has yet isolated it. Last year Schäffer, in London, and Roos, in Freiburg, demonstrated that the therapeutical and physiological effects of the thyroid gland are not injured by boiling it, or by the action of ten-per-cent. solution of hydrochloric acid or of caustic soda; we know also that the effect obtained is the same whether the thyroid extract is injected or whether it or the thyroid gland be given by the mouth, which shows that the active principle is not destroyed by the pepsin and trypsin ferments.

The only way to solve this problem is to find the active principle by exact chemical methods, and then to study the body so found; but this is a very difficult thing for the chemist, as we have no chemical reaction for the active principle, and no analogies to guide us. The only way left is to test experimentally every substance found, and this I have done with success.

I prepared cold or warm extracts of known quantities of dried sheep's thyroid. The albuminous bodies were precipitated by acetic acid. It was then necessary to determine whether the precipitated bodies (albumin and nucleo-albumin) or their filtrates were the active agents. This I did by feeding the first, well washed, to two corpulent men and a fat dog. Notwithstanding that I fed the albuminous bodies from the extract of seven sheep's thyroids every day for ten

consecutive days to each man and to the dog, they showed no change in weight. The filtrate, however, was active. I, myself, drank daily the neutralized filtrate, and lost three hundred grammes in weight each day for six days, in addition to which I noted a marked acceleration of pulse. The same result was obtained in another person, thereby proving the important fact that the active principle does not reside in the albuminous bodies, but in the filtrate.

I began now the chemical examination of the filtrate free from albumin. By evaporation a syrup was obtained, which became gelatinous on cooling, showing that gelatin from the connective tissue of the thyroid was present; experiments made with this gelatin showed that it was inactive. I could now proceed in a shorter way by precipitating together the inactive albuminous and gelatinous bodies. These substances were precipitated from the maceration or decoction of the gland with neutral sugar of lead, the precipitate was filtered, and the lead was removed from the filtrate by sulphuretted hydrogen. The syrup was now dissolved in alcohol, and by ether or acetone one could precipitate a large quantity, which, when cleaned and crystallized, showed the following physical and chemical peculiarities: It is very hygroscopic, and the crystals are permanent only in the dried part; it dissolves in water and alcohol, but not in acetone or ether. The watery solution has a neutral or weakly alkaline reaction; it is precipitated neither by sugar of lead nor by sub-acetate of lead, but, on the other hand, precipitation occurs with the reagents of the alkaloids, potassium iodide of mercury, potassium iodide of bismuth, phosphotungstic acid, and phosphomolybdic acid; by decomposition of the precipitates of both the latter acids with barium hydrate the free base can be obtained in the form of a markedly hygroscopic syrup. Iodo-potassium iodide and tannin give no precipitate. The chlorides of gold, platinum, and mercury give a slowly falling precipitate in a watery solution. The addition of an alcohol sublimate solution to the alcoholic solution of this body produces an intense white precipitate. With Millon's reagent the substance gives a precipitate, but there is no red color when it is boiled for a long time. There is no precipitate with picric acid. When it is shaken with a solution of caustic soda and benzoyl chloride, we obtain a benzoyl derivative, soluble in ether. Bromine water gives a white precipitate, but no precipitate is formed with an ammoniacal silver solution. Nitrate of silver gives a precipitate which dissolves again in ammonia or on boiling. The substance gives no reaction with the nitrocyanoide of sodium; there are no reaction of Weidel with chlorine water, no reaction by evaporating with nitric acid and afterward adding caustic soda, and no reduction by copper oxide in an alkaline solution. There is a precipitate when boiled with acetate of copper, and a precipitation also occurs with salts of copper oxide, by adding to the watery solution a mixture of copper sulphate and bisulphide of sodium.

The elementary analysis of the acetic salt gave: C, 35.64 per cent.; H, 5.56 per cent.; N, 20.5 per cent. This led to the empirical formula, $C_6H_{11}N_3O_5$. Aliphatic bases of this constitution with N_3 have until now been described only as derivatives of guanidin or

¹ Preliminary report read before the Society of Physicians of Vienna, November 22, 1895.

succinic acid. Theoretically both deductions were possible. Against the hypothesis that the body in this case was a guanidin derivative is the fact that it did not precipitate with an ammoniacal silver solution. On the other hand, what speaks for its being a guanidin derivative is the occurrence of its bromide, which is insoluble in water, and also the fact that it is precipitated with acetate of copper or with oxide of copper. The study of the salts and the composition of the substance found will determine the question in regard to its constitution, and it may be possible to make the substance by synthesis.

I have provisionally named this pure substance, according to its physiological action, thyreoantitoxin, until such time as I can give it its proper chemical name.

Although there was no doubt in my mind that this pure body really was the active principle, since in my whole investigation I have found this substance only, and in considerable quantity, in the active filtrate, I have endeavored to prove experimentally the identity of this substance with the active principle.

There were three ways in which these bodies might be tested. They might first be proved clinically, but this method was too slow, and, furthermore, I had no material. Such experiments are, however, now being made. The other methods are purely experimental. Schäffer, of London, has found a remarkable fall of blood pressure following intravenous injection of thyroid extract, and Haskovetz, of Prague, also noted this fall of blood pressure and acceleration of the pulse. But I have found, either with the cold aqueous extract of dried sheep's thyroid or with my pure substance, no fall of blood pressure, though I did find an acceleration of the pulse. I do not know what is the explanation of this difference, but shall make further investigations to determine. In a morphinized dog, an increase was noted in the pulse-rate from 56 to 80, 120, or even 140 per minute, from which it can be seen that the pure substance produced the same effect as the fresh extract in the experiments of Haskovetz.

Some experiments made upon the hearts of frogs, poisoned with muscarine, in which pulsation had ceased, showed that a few drops of the watery solution of thyreoantitoxin caused them to beat again. Another method which I have employed is the following: As kittens are the animals most affected by removal of the thyroid gland, I chose them for experiment, removing from a number both thyroid glands. As soon as the animals began to have severe cramps, I injected subcutaneously a one-per-cent. watery solution of thyreoantitoxin. The result was in some cases most striking. In a few minutes the whole appearance was changed; the kittens, which had been lying with irregular respiration and with reflexes abolished, began again to breathe rapidly, the reflexes returned, the rigidity of the extremities disappeared, and the animals quickly recovered. In some cases the cramps did not return; in some they did, but ceased after a second injection. In some cases I made an injection of the solution immediately after the thyroidectomy; these animals did not suffer from cramps. These experiments agree with those made by Gley in Paris. He could not, of course, prevent death, in animals deprived of the thyroid, by means of the injection of thyroid juice; neither could I by injections of the pure substance. He obtained the following results: If an injection of thyroid juice into the jugular were made after the operation, there were no convulsions, although the animals died. Rabbits are an exception to this rule, for in them the cramps are noticed even after the injection. In a number of cases Gley made the injection only after the appearance of severe convulsions; in these cases the convulsions ceased ten minutes later and the respiration resumed

its normal rhythm, but all the animals died. In a number of cases there was no result observed after injection, and the same is true of healthy animals operated upon, except that in one instance the injections caused a trophic affection of the skin.

This demonstrates the fact that the active substance of thyroid gland is a pure chemical body, of well-defined chemical properties, present in considerable quantity in the gland substance; and it will prove to be the body which contains all the therapeutic properties of the thyroid gland, the more so as its action on the circulation is sufficient to explain all its other action as regards resorption and metabolism.

We are now able to give therapeutically in exact doses a pure chemical body, instead of the thyroid gland or its extracts, the composition and the quantity of the active principle of which we do not know. We are furthermore not sure that these crude preparations are free from ptomaines; only recently a case of malignant edema following thyroid feeding has been reported. The active principle is odorless, and its taste is like that of an extract of beef. The clinician can now experiment with this pure substance, and exclude many of the cases where either no action at all or some injury has been produced. It must furthermore be remembered that many of the thyroid preparations on the market are inert, in consequence of faulty methods of preparation.

The result of this investigation shows that chemical analysis only, combined with clinical experiment, can explain the physiological and therapeutical actions of the organic extracts. There is no doubt that chemical investigation of other organs and of blood serum will show that there are still many unrecognized chemical bodies present in small amount in the organism which exert a powerful influence in the way of protection against infection, a fact which has already been proved with regard to antitoxic serum.

The time is not far off when a chemist can make these pure substances and afterward prove them experimentally, perhaps make them synthetically, and so give to the physician many new drugs in a pure form and one that will permit of exact dosage.

PROLAPSUS OF THE RECTUM WITH SPECIAL REFERENCE TO ITS OBSCURE FORMS AND SOME OF THEIR REFLEX PHENOMENA.¹

By JAMES P. TUTTLE, M.D.,

ADJUNCT PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC.

PROLAPSE of the rectum is a disorder so familiar to the profession in its more frequent manifestations, that it would be presumption for me to take up the time of this Society with a paper devoted to the general condition.

I shall endeavor, however, to emphasize the importance of one of the varieties which is not generally recognized, and which many believe to be of little consequence.

We may divide the subject of prolapsus into the complete and incomplete. The incomplete involves the prolapse of only the mucous membrane of the rectum (Fig. 1). It is simply an exaggeration of a physiological process which takes place at every defecation.

As will be apparent to every one familiar with the anatomy of the rectum, it can only extend to a certain degree without involving the other coats of the bowel, because its attachments to the muscular layer are at most very short, one and one-half inches to two and

¹ Read before the New York County Medical Society, December 23, 1895.

one-half inches being about the limit of such prolapsus. It may be due to polypi, hemorrhoids, adenomata, or other neoplasms of the rectum. It is sometimes due to phimosis, stricture, stone, cystitis, enlarged prostate, or anything which produces severe spasm of the sphincter muscles, or bearing-down strain.

It is also sometimes due to ulceration, fissure, and other inflammatory diseases, and may be produced by chronic constipation or severe diarrhœal disease, either of which involves long sitting at stool. Its diagnosis is very simple. It always occurs gradually, never suddenly, is of a bright red, or sometimes dark congested hue, and surrounds the anus with mucous folds radiating toward the centre. It may, if it has existed for any length of time, have more or less excoriation or ulceration upon its surface; indeed, the inflammation in it has at times been so

FIG. 1.—Incomplete Prolapse.

great as to produce sloughing of the whole membrane. There are generally no constitutional symptoms associated with it, except where severe inflammation complicates the disorder. The pain is very slight, and unless hemorrhoids are associated with it there is seldom any bleeding.

The prolapse is generally reduced automatically after stool, or at least can be reduced by the patient himself with little difficulty. It is rarely found in adults, but frequently seen in young children and very old people. In the latter it sometimes becomes permanent, rarely irreducible, but recurring in a few moments after it has been replaced. Its treatment consists, first, in the removal of the cause.

Hemorrhoids, neoplasms, ulcerations, stone, phimosis, fissure, stricture, and cystitis should be treated when any of these conditions exist, and in the majority of cases their cure will be followed by the relief of the prolapsus of the rectum. Where it is due to catarrhal disease of the rectum, irrigation of that organ with local applications, suitable to the particular form of catarrhal disorder, and treatment directed toward regulating the intestinal functions should be carried out. At the same time cold applications should be made to the parts two or three times a day, especially after the bowels move. A small compress should be applied over the anus and the buttocks strapped together with an adhesive strap. Move bowels in the recumbent posture. In the majority of cases these procedures will result in a cure. When, however, the condition has become chronic and there is more or less hypertrophy of the submucosa, something more radical needs to be done. The hypodermic injection of various therapeutic agents has been recommended from time to time, among them nux vomica, strychnine, ergot, and carbolic acid. My own experience is confined to the use of carbolic acid. I have used this agent in a number of cases in the form of the modified Shuford's solution, and have met with the most gratifying results in all of them. I introduce the needle at the muco-cutaneous border and carry it up as high as the point at which the prolapse begins, and withdrawing it I inject minute quantities of the fluid all along its track. This procedure is repeated at four points about the anus. It is necessary to add that the utmost antiseptic precautions should be taken in doing this, as any septic material surrounding the anus may be carried in upon the point of the needle, and thus infect the injected area. Again, comparatively small quantities of the fluid should be injected; five minims is the limit of what should be introduced at one point, and where the procidentia is only slight, two or three minims will always suffice. Where the

condition is uncomplicated I have not found any more radical measure necessary in these cases; but where neoplasms, or hemorrhoids, or deep ulcerations are associated with the disease, one or the other of the surgical procedures for its relief are advisable. With hemorrhoidal complication, any of the three popular methods, the clamp and cautery, the ligature, or the so-called Whitehead operation, will eradicate the prolapsus at the same time it cures the hemorrhoids. Personally, I prefer the clamp and cautery in this condition, but have seen excellent results from both of the other methods.

Where there are no hemorrhoids, and where the condition is associated with hypertrophy and relaxation of the sphincter, the clamp and cautery, applied to several folds of the prolapse, are in my judgment the most successful as well as the most scientific method of treatment for this the incomplet form of prolapsus.

Complete Prolapsus.—The complete form of this disorder involves the prolapse of the rectum in all its tunics, and may or may not protrude through the anus. There are three degrees of this condition, as shown in the figures here presented, and numbered accordingly.

1st. Prolapse beginning at the margin of the anus in which the external surface of the prolapse is continuous with the external tunic of the anal orifice (Fig. 2).

2d. Prolapse beginning at a point more or less removed from the anus and protruding through that orifice (Fig. 3).

3d. Prolapse beginning at a point more or less remote from the anus, the prolapsed portion of the gut occupying the ampulla of the rectum, but not protruding through the anus.

The first degree of this variety is due to the same causes as the incomplete prolapsus, indeed it is frequently a sequence to the latter and comes on after it has existed for some length of time. Its diagnosis is simple. The mucous folds, which in the incomplete variety run up and down, radiating toward the centre, now become circular and surround the prolapsing organ in crescentic folds. Its color, when at first protruded, is a bright arterial red, but after it has been down for a short time it assumes the dull purplish hue associated with venous turgescence.

Percussion will be dull, unless the prolapse is of considerable extent and a hernia exists. The orifice

FIG. 2.—Complete Prolapse, 1st degree.

FIG. 3.—Complete Prolapse, 2d degree.

of the prolapsed gut will point straight downward until a sufficient length has come down to cause dragging on the meso-rectum, when the orifice will begin to point backward toward the sacrum.

Where the disease is associated with new growths, the prolapse will only extend to such a degree as to bring the attachments of these growths to its most dependent margin. Excoriation, ulceration, acute inflammation are frequent complications of this and the following variety of the disease. There is generally a mucous discharge, which irritates the surrounding

parts, and there may be more or less superficial bleeding. The treatment for this degree and the succeeding one is identical, and therefore we will consider it under that heading.

Second degree: Where the prolapse begins at a point more or less removed from the anus, and the rectum protrudes through that orifice, there will exist, between the margin of the anus and the protruding gut, a sulcus, or space, into which can be introduced a probe or sometimes even the finger to the height at which the prolapse begins.

This variety of the disorder may appear gradually, but in the majority of cases it is of sudden occurrence, due to some violent strain, crushing accident, fall, or other injury. Its extent is limited only by the length of the colon itself, or even of the small intestine. When the protrusion first appears at the anus its orifice points straight downward, but soon traction upon the meso-rectum begins to draw it backward, and as the prolapse increases, the meso-sigmoid and meso-colon each in its turn drawing upon the prolapsed organ, twist it in a sort of corkscrew shape, sometimes making as high as two or three complete circles. The general appearance and symptoms are the same as those of the first degree, and it is unnecessary to repeat them here. The complications of this variety are numerous and serious. Archocoele or rectal hernia is a frequent occurrence and is diagnosed by its resonance upon percussion, the gurgling sound upon palpation, and its disappearance when the patient is put in the knee-breast posture. Strangulation, ulceration, and gangrene are frequent complications where this condition is not properly treated. Catarrhal inflammation with its consequent excoriation and superficial ulceration is one of the most trying complications of this disorder. The mucous discharge irritates the external parts, and these parts rub upon the prolapse until inflammatory hypertrophy supervenes, replacement of the prolapse becomes impossible, and the patient is miserable indeed. Rupture of the rectal wall and protrusion of the coils of small intestine through the rent have not infrequently been seen.

One of the conditions connected with this complication is that wherever it has been seen to occur, the prolapse of the rectum is immediately automatically reduced. No explanation for this strange condition has yet been given.

Sometimes this form of prolapse takes on an appearance resembling carcinoma of the rectum, and so much like it does it appear that sometimes only microscopic examination will determine its real character.

The diagnosis of prolapse of the rectum in any of the degrees in which the organ protrudes from the anal aperture is dependent upon a simple ocular and manual examination, and while it may be due to piles, tumors, etc., it is still prolapsus of the rectum and should be treated accordingly.

The operative treatment of these conditions will be discussed under the next variety, but it is well to say here that no operation should ever be undertaken in acute or moderate, reducible cases until the adhesive-strap method revived by Dr. Powell, of this city, has been given a fair trial. By proper attention to the inducing and predisposing causes, in order to prevent recurrence, and to the general health and muscular tonicity of the parts, the large majority of these simple cases may be cured without operation. The strap method, however, is useless in the obscure following variety:

Third degree: Prolapse of the rectum where it does not protrude through the anal aperture has been denied by some writers, belittled by many, and acknowledged as a disorder of any importance by only one author, so far as I am aware.

Dr. Cripps, in his excellent work upon disease of the rectum, describes in a short paragraph this disorder as he has observed it, and clearly indicates the importance which he attaches to it. It is to this paragraph that I am indebted for whatever interest I have taken in this form of the disease, and I gladly accord to its author any credit which may accrue from these studies.

As will be seen from the description, this degree of the disorder may be called an intussusception of the sigmoid or upper portion of the rectum into the lower. Indeed, it may be the commencement of the second degree; but the symptoms which indicate its existence belong essentially to it alone.

FIG. 4.—Complete Prolapse, 3d degree.

It consists in the dragging down or procidentia of the sigmoid flexure or upper portion of the rectum into the lower portion to greater or less extent. There is no external appearance of the intestine at the anal aperture. The patient has no sensation of a foreign body in the anus, no unusual protrusion of the mucous membrane at stool, and, indeed, no indication that the rectum is in any way displaced. The symptoms of which he complains are purely subjective, and in many cases have no reference whatever to the lower end of the colon. He may suffer from diarrhoea or constipation; but with whatever condition, he will give the same account, that, when at stool, he never feels as though he were finished, but that there appears to be always something more to come away. This feeling of "unfinished business" is the most common symptom of the disease and of the utmost importance in diagnosis. Enemas are essential to a movement of the bowels, and act more by raising the fallen gut than by stimulating peristalsis.

Pains in the sacral region, and radiating down the thighs, are frequently the chief complaints of these patients. At other times, there is aching of the perineum, with disorders of micturition and sexual functions. In a number of cases I have elicited a dragging in the lower abdominal region, which more than once has been attributed to ovarian or tubal disease. These are all symptoms located in and about the parts affected, but there are others which are more remote and of deeper interest to the general practitioner. Flatulence, symptoms of chronic entero-colitis, and indigestion are frequently associated with this disorder, and cured, or at least greatly benefited, by its relief. In fact, I have yet to see one that has not complained of indigestion of some form and a feeling of fulness in the abdomen, generally in the region of the descending colon.

Periodic discharge of mucus with the stools, associated with more or less exhaustion and sometimes severe abdominal pains after stool, are some other reflex manifestations of this degree of prolapsus.

I will not occupy your time by detailing any series of cases, but recall only one marked example of this condition.

Mr. T—, a merchant, thirty-two years of age, has suffered with digestive troubles for the past five years. He has been alternately constipated and affected with diarrhoea. After eating he has an immediate desire to go to stool, yet frequently without any result. His bowels have been constantly distended with gases, and frequently at defecation he passes large quantities of mucus. Has never noticed any blood. For the past two years he has suffered constantly from pain in the lumbar and sacral regions. Recently these pains have extended down his legs. For the last six months

he has noticed an increasing sexual weakness associated with some difficulty or delay in micturition. All treatment directed to his stomach, kidneys, and other internal organs has been of no avail. Even when he has suffered from diarrhoea he has felt a desire to remain at stool just as much as when he was constipated, feeling always the sensation of something yet to come.

Careful examination failed to reveal any organic disease in his heart, lungs, stomach, or kidneys.

Examination of the rectum showed nothing abnormal about the anus or within the first inch and a half of the organ. About this point, however, the finger came upon loose, flabby folds of mucous membrane crowded down into the rectal ampulla, through which it was very difficult to find the lumen of the intestine with the finger.

Placing the patient in a squatting position, and asking him to strain, the finger introduced into his rectum felt the upper portion of that organ distinctly to descend and impinge upon its end, like the soft dilated cervix of the uterus.

A rectal bougie of moderate size (No. 7) could be introduced about six inches before it came in contact with an absolute obstruction. By gentle pressure on the bougie, and a stream of water carried through it with the aid of a Davidson syringe, the instrument was eventually introduced to its full length, and examination of the rectum with the finger after this, revealed an enormously dilated ampulla, large enough to contain the head of a six-months foetus. A larger bougie (No. 9) was arrested at eight inches from the anus, and it was impossible, without undue force, to push it past this point.

Twenty-four hours later, under chloroform, the sphincters were dilated, and the hand introduced in the rectum, where the whole upper portion or sigmoid flexure was found prolapsed into the ampulla.

The lower entrance of the sigmoid flexure was distinctly contracted, so that it was with difficulty I could introduce two fingers through its lumen. Having done this, however, I could drag down the organ to the very margin of the anus without any force.

Introducing one finger after the other through this stricture at the lower end of the sigmoid, I dilated it as far as safety would permit and then easily introduced a No. 12 bougie to its full length. This was clearly a case of complete prolapsus of the rectum of the third degree, associated with or due to stricture of the sigmoid flexure. The treatment, which I will detail shortly, was followed by complete relief of all the patient's symptoms, and to-day he is perfectly well. This is but one of a number of such cases, many of them having more or less contraction at the lower end of the sigmoid, at the location of the so-called third sphincter. Indeed, I have rarely failed to find a slight narrowing of the lumen at this point. Other more remote and properly reflex symptoms, may be mentioned in this connection. I have seen neuralgia of the testis relieved by the restoration of this third degree of prolapse. One patient whom I might mention, without detailing history, was unable to urinate while he was at stool, notwithstanding the extreme desire to do so. It was necessary for him to urinate before defecation in order to have any comfort in the latter act. This inconvenience was also relieved by the restoration of a prolapsing rectum. Vague and indefinite pains in the loins, abdomen, and sometimes as high up as the transverse colon and scapula, have been complained of by patients suffering with this disorder, and have been relieved after treatment for it, although I am not prepared to say that they were all due to the condition itself.

The facts that in all the cases which I have treated there has been carried out dietary and anti-dyspeptic

regimen, and that their digestions have all been greatly benefited, either by the treatment of the rectum or by that directed to this condition, leave an uncertain inference as to how much influence the reposition of the rectum had upon the digestive functions. All that I can say upon this point is that treatment directed to the digestive organs previously had failed. What I desire is not to exploit any remarkable results, but rather to call attention to the frequency of this form of procidentia, and to emphasize the positive as associated with the vague and reflex symptoms of the disease. Constipation, periodical discharge of mucus, sensation of incompletely defecated, weight and aching in the sacral region, dilated rectal ampulla, and the other physical evidences elicited by digital examination are the cardinal points in diagnosis, and, while many of them belong to other conditions, when associated as a group they point unerringly to this obscure form of prolapsus recti.

The older treatments for the first and second degrees of complete prolapsus are so thoroughly detailed in the treatises upon surgery and rectal diseases that it would be a sacrifice of your time for me to attempt to describe them in detail. In order, however, to understand the basis upon which the new methods rest, it may be well for us to refer to the conditions upon which the disorder depends. The rectum is maintained in its position by two varieties of supports, the passive and the active. The passive are formed by connective-tissue fibres, scattered or in bundles, and elastic-tissue fibres, formed by the peritoneal folds, and also by the blood-vessels which supply the organ. The active supports are composed of striated and smooth muscular fibres. The striated fibres are found in the longitudinal and circular muscles of the rectum itself, the smooth in the sphincters and levator ani. Nosologically, prolapse of the rectum is akin to hernia, and, like this disorder, cannot occur without some weakening of its supports or destruction of its means of fixation, as well as some determining force capable of dislodging from its normal position an organ loosened and relaxed in its attachments. The weakening or destruction of each of these two classes of supports has a different source and distinct significance. The passive supports lose their efficiency through being elongated or broken; the muscular supports lose theirs through atrophy, or partial or complete paralysis. It is rare that all of the supports should yield at once; but in view of the number of cases in which prolapsus has followed a severe strain or a crushing accident, without any previous symptoms of such a condition having existed, we cannot deny that occasionally they do. But the history of the cases will nearly always clearly indicate whether they be due to relaxation of the superior passive supports, originally, or to relaxation and atrophy of the active or muscular supports. Having determined which of these causes is responsible for the condition, we should direct our treatment to the restoration of the parts originally offending, and treat the others as simple participants.

Paralysis of the intestinal wall itself bears in its train constipation, fecal retention, and dilatation, so that the organ is elongated, or actually hypertrophied in length, and we may have a simple prolapse of the rectum of unusual extent in which the sigmoid and the upper colon are in no wise involved.

Exposure of the mucous membrane and its consequent friction set up a catarrhal inflammation or recto-colitis, with its consequent tenesmus, diarrhoea, and efforts at expulsion which tend to reproduce the disorder when it has been reduced, and militate greatly against any effectual treatment; yet sometimes this very condition of catarrhal inflammation of the

rectum is the exciting cause and not the result of proidentia. This is an element to be taken into consideration in our treatment of these cases. The principles in the modern treatment of this condition are: First, to remove, if possible, any pathological causes. Second, to re-establish the supports which have been elongated or destroyed. Third, to control, or cause to cease, the efforts that force the organ outside.

The accomplishment of these ends is by no means easy, and I question if it will ever be fully done. Nevertheless, I believe we are advancing toward that point. But so far, I believe, we have paid too little attention to those causes which tend to reproduce the disorder where once it has been reduced.

In prolapse of the first degree, where the lower segment of the rectum descends first, and the upper segments follow, the elongation of the latter is clearly due to traction upon them by the weight of the rectum loosened from its lower attachments. In these cases, our aim should be to re-establish the normal condition of the parts which first gave way, and trust, for the time, to the restorative power of nature for the retraction and shortening of the elongated upper supports. When the adhesive strap has failed we have an efficient means of doing this in the Van Buren operation, which, as you know, consists in linear cauterization of the rectum with the actual cautery. I have seen it stated in certain well-known books that the Paquelin cautery is not suitable for this operation. I have used it many times for this purpose, and find it to fulfil every requirement. The injection of the therapeutic agents mentioned for the incomplete prolapsus I have never used in this condition, but I cannot see why they may not be as efficient as is claimed by Vidal, Kelsey, and others.

Dr. Allingham's method of applying fuming nitric acid to the whole circumference of the prolapsing organ has seemed to me a rash procedure, for we cannot limit the depth to which the acid burns or check its extent to the muco-cutaneous surface, where it produces great inflammation and severe pain.

In several cases, I have used this agent, applying it in lines up and down the prolapsus, at four or five points about the circumference. These cases have all been in children, and the results have been entirely satisfactory.

These same procedures are applicable to the second degree of prolapsus, but an added precaution is necessary when the prolapse contains a hernia, or is of sufficient extent to involve any degree of the peritoneal cul-de-sac. In such conditions, cauterizing too deeply may produce peritonitis, or if the hernia should be present in the sac at the time, inflammation and gangrene of the intestine itself. No cautery or hypodermic injection for the cure of this disorder should ever be used until it is ascertained that the prolapse can be fully and completely reduced. Partial reduction is not sufficient, and may involve the most serious consequences. The methods of reducing these prolapses are numerous. The simplest and most efficient which I have ever used consists in wrapping a piece of tissue paper around the point of a small Wales bougie, introducing this into the orifice of the prolapse and gently pressing it upward, while a stream of water is carried through it, the prolapse itself having been previously well lubricated with vaseline or other agent. After the parts have been restored in this manner, gently twisting the bougie will loosen it from its paper wrapping and it can be withdrawn. The finger may supply the place of the bougie in cases of slight prolapsus. The hips should be elevated, the knee-breast posture being the most efficient in this procedure.

It is not necessary to state that these methods often fail to effect a cure, and that much more radical meas-

ures are sometimes necessary to obtain even comparative comfort for our patients, not to say radical cure.

Amputation or resection of the organ has been done, and the several different methods, which go by the names of their originators, are described in the works upon this subject. Various plastic operations, such as the Roberts-Dieffenbach method, which consists in removing a V-shaped piece from the posterior wall of the rectum and from the ano-coccygeal space and suturing the parts together, have been performed with more or less success.

Rectopexie, which consists in suturing the rectum to the sacral surface, has been attempted several times by Verneuil and other surgeons; but with only comparative success. The operation of Mikulicz,¹ variously modified by Lange, Keene, Brandt, Nélaton, and others, has, until recent years, been considered the last resource in grave and rebellious cases.

Since, however, aseptic surgery has rendered the invasion of the peritoneum so free from danger, the operation of resection by one of these various methods has become a less formidable one, and it may be undertaken with comparative assurance of success in patients of operable age.

The techniques of these different operations are fully described in the works upon surgery and diseases of the rectum, and I shall not detail them here.

It must not be presumed that end-to-end suturing of a diseased intestine within the peritoneal area can be attempted without great danger to the patient, and if any procedure could be devised which would accomplish the desired end without opening the intestine it would be most desirable.

In obstinate and serious cases heretofore, having little control over the elementary lesions, and being unable to shorten the superior supports or to reanimate the muscular fibres, we have been forced to deal with their symptoms or results by operative means, often quite insufficient or of a passing efficacy.

I am confident that many of our failures have been due to the neglect of the proper measures against constipation, laborious and repeated efforts at defecation, proctitis, diarrhoea, and the other disorders which create and continue peristaltic action and desire to go to stool.

With proper attention to these conditions, I believe that the majority of cases of the first and second degrees of prolapse would be relieved by the simpler methods which I have detailed.

Within the last five years, however, the study and practice of a new method for overcoming this disorder have been carried out by a number of surgeons, apparently independent of each other.

In 1888, I began a series of experiments upon the cadaver to determine whether or not the meso-rectum could be drawn up and sutured to the abdominal wall in sufficient extent to produce an adhesion between the peritoneal surfaces strong enough to maintain the organ in its position. I have examined twenty-five cases and have found that in eighty per cent. the meso-rectum can be drawn up and sutured to the abdominal wall to the extent of about two inches. I have had a number of cases of prolapsus in the mean time, but only one of them was sufficiently severe to justify me in recommending such a serious operation. The results from this have been all that could be desired, there having been no recurrence in nearly two years.

In 1890, Dr. Jaennel, of Toulouse, devised the operation of colopexie, and Dr. Verneuil, of Paris, was the first to carry it into execution. The method consists in suturing the colon into the inguinal wound, having drawn it up so far from the pelvis that it supports the prolapsus. The first case was successful.

¹ Langenbeck's Archiv, 1888.

In the second case, without any reason given in the paper,¹ he modified the operation, doing what he terms colopexotomy, which consists simply in dragging the colon up to such an extent that it supports the prolapsing rectum, and making an inguinal anus, thus affording physiological rest to the diseased organ. By this method he reports complete success, and believes that it will be the future operation in grave and obstinate cases. The objection to this operation lies in the difficulty of closing the artificial anus.

In 1894, Dr. Joseph Bryant, of this city, performed an ordinary inguinal colotomy on a patient suffering from extreme prolapsus, with the simple view of giving the parts complete rest, and was surprised to find that the prolapsus was apparently cured after a short period. I have heard indirectly that it has since recurred, but am unable to state this positively.

John Berg, of Stockholm, operated by suturing the meso-rectum to the abdominal wall in 1892. He describes this method as that of Jaennel. It is not, however, the same, being nothing more or less than the method which I have experimented upon since 1888.

Up to the time of writing his paper Berg's case has remained perfectly cured.

In 1893, Dr. Blank, of Melbourne, operated upon two cases according to this method, with excellent results.

Within the past year four cases have been operated on by this method in New York, but as they have not been published, I have no authority to repeat them here. I have had the good fortune to see one of these cases, in which the condition had recurred, re-operated upon. It was associated with an adhesion between the rectum and a hypertrophied prolapsing uterus. The weight of the uterus had elongated the meso-rectum and its adhesions to the abdominal wall, but had not torn them loose, and I am sure that had the uterine condition been normal the prolapsus would never have occurred. This case suggests the advisability of abdominal fixation of the uterus at the same time the colopexie is done. The technique of this operation consists in the ordinary preparation of the patient for colotomy, and an incision about two inches internal to that for inguinal colotomy. The meso-rectum is then caught and dragged upward until the prolapsus is completely reduced. It is slightly scarified and sutured to the peritoneum at the external margin of the wound to the extent of about two linear inches. The sutures should run parallel with the blood-vessel, but it must not be forgotten that at this point the blood supply of the rectum comes from the inferior mesenteric artery. It runs close to the intestine, in the fold of the meso-rectum, and parallel with the longitudinal axis of the gut.

The colon should fall inward from the sutured area. The wound should then be closed as in ordinary abdominal section. The bowels should be moved only by enemata for the following three weeks, and the patient kept absolutely in bed.

Further observations are necessary to draw any definite conclusions from this operation, but as it relieves all tension upon the superior supports, and takes away pressure from the sphincter muscles, it would seem that it is based upon scientific and mechanical reasons, and is destined to do much for the obstinate cases of this disorder. It should at the same time be supplemented by remedies and methods directed toward restoring the tone of the muscular supports and overcoming any disease or condition which leads to reproduction of the disorder. The operation, however, should never be advised except in grave and rebellious cases. It is inapplicable to recent, irreducible, adherent or strangulated cases, or to those where the wall of the gut is so weakened by disease that it might be torn by our efforts at retraction.

¹ Gazette Hebdomad. Méd., Paris, 2 s., 1890, xxvii., p. 246.

Little attention has so far been paid to the treatment of the third degree of complete prolapsus. Its symptoms are usually not severe enough to call for such radical operations, but its victims suffer from vague and indescribable pains and discomforts and demand more careful consideration than they generally receive. In the past five years I have seen a comparatively large number of these cases, over fifty, and have found that by removing, if possible, the exciting cause, regulating the functional action of the bowels, properly treating any catarrhal or inflammatory condition that exists in the rectum, and persistently replacing the prolapsed portion of the gut, temporary cure at least may be obtained. Dr. Cripps advises the Van Buren operation in these cases, but I have found it very seldom necessary. The method which I have employed consists in reducing the prolapsus by the introduction of a full-sized Wales bougie, according to the method described above. As soon as the bougie has been passed to its full extent, the colon is flushed with a twenty-five-per-cent. saturated solution of boric acid, about a quart of the fluid being used. This flushing is followed by an immediate action of the bowels, after which the bougie is re-introduced and one ounce of a two-per-cent. mixture of aristol in almond oil is injected into the colon. Boric acid and salol, five grains each, are administered after each meal, two drachms of phosphate of soda are given in hot water before breakfast each morning, and careful attention to the diet and digestive functions is enjoined. These methods, though extremely simple, require care, and sometimes the greatest patience must be exercised before the bougie can be introduced or the prolapsus restored.

Nevertheless, with such care and patience, I have obtained the most excellent results.

It may be asked, what is to prevent the prolapse from immediately recurring, after it has been thus reduced? Nothing, I would answer, if the rectum were a straight tube, from the promontory of the sacrum to the anus, as is described in most anatomies, and the sigmoid flexure an abdominal organ as is generally assumed: but a large number of examinations have proved to my mind that the major portion, in fact three-fourths, of the sigmoid flexure lies in the pelvic cavity and passes off from the rectum, transversely, at an acute angle, and if it has been once reduced, the force of gravity does not tend to carry it down through the rectal lumen, but rather beside that organ, and only when peristaltic action and straining have been resumed will the prolapsus recur. Therefore the measures directed toward soothing the irritations in the colon and rectum, and quieting all tendency toward tenesmus and straining, are of the utmost importance.

Many of these cases are associated with fissures and rectal ulcerations, and the proper treatment of these conditions should be carried out at the same time that our attention is directed to the prolapsus.

I am convinced that this condition of the third degree of prolapsus is far more frequent and of much greater importance than is usually recognized by the profession, and a more careful analysis of symptoms and more regular local examination will reveal it to be the cause of many of the vague symptoms and indescribable discomforts of our chronic cases, and also that the patient and persistent application of the simple method here detailed will add much to the alleviation of symptoms, even though it may not effect a permanent cure.

Many of my patients consider themselves well, their symptoms having been relieved, and have removed from my observation; others I have kept track of, and find that after one to two years the prolapse has not recurred.

TETANY, WITH REPORT OF FIVE CASES.

By WILLIAM C. KRAUSS, M.D.,

BUFFALO, NEW YORK,

PROFESSOR OF NERVOUS DISEASES, MEDICAL DEPARTMENT OF NIAGARA UNIVERSITY; NEUROLOGIST TO THE ERIE COUNTY HOSPITAL; FELLOW OF THE AMERICAN NEUROLOGICAL ASSOCIATION.

TETANY, or bilateral tonic spasms usually of the extremities without loss of consciousness, is an affection extremely rare not only in America but also in England, Germany, Italy, and Spain. Gowers, of London, with a plethora of nervous cases at his command, was able to report only 8 personal cases and collected but 142 cases from various sources; Ewald, of Berlin, out of 8,000 cases entering the Kaiserin-Augusta Hospital detected but 2 cases of tetany; Bernhardt, of Berlin, regards it as one of the rarest of nervous affections, he having seen but 3 cases. In France it has been reported as occurring epidemically among young girls, 30 having been seized in one school. Epidemics have also broken out in Belgian prisons, suggesting a tendency undoubtedly to some obscure epidemic influence. In Austria and Bohemia, on the other hand, it is of common occurrence in the larger cities, especially Prague and Vienna. Frankl-Hochwart, of Vienna, reported recently 70 cases, nearly all of which were observed in the Nothnagel Clinic. Schlesinger, of Vienna, and v. Jaksch, of Prague, each have made careful observations based on a large number of personal cases, showing its undoubted prevalence in these countries.

In view of these facts showing such rare occurrence of this malady, with the exception of the Austrian empire, it is interesting to note that in the private practice of Dr. Albert H. Briggs, ex-health commissioner of Buffalo, five cases occurred within a period of three months, one of which was kindly referred to me for special treatment. Before reporting this case and the other four cases as reported to me by Dr. Briggs, a glance at the symptomatology of tetany may not be amiss.

The spasms are sometimes ushered in by sensations of numbness, pain, or formication in the extremities, followed by a sudden contraction, especially of the flexor muscles of the upper and lower extremities, without the least impairment of consciousness. The hands are more often affected than the feet, and the spasmodic contraction of the interossei and of the adductor pollicis gives the hand a peculiar appearance quite characteristic of this disease (Fig. 1). The

FIG. 1.—Position of Hand in Tetany.

hand is generally flexed upon the forearm and at times the arm is flexed at the elbow. In the foot the same general condition is observed: the toes are strongly flexed and the foot is brought into the position of equino-varus (Fig. 2). Occasionally and in very severe cases the diaphragm, tongue, larynx, and respiratory muscles may become involved and in rare cases even the ocular muscles, producing a temporary strabismus.

The spasms which are always bilateral vary in duration from a few minutes to hours, days, and even weeks according to the severity of the disease, while

the interval between succeeding spasms may range from minutes to weeks or there may be no distinct interval between the attacks (continuous type), the spasm presenting periods of relaxation and exacerbations.

With the exception of the pain due to the forcible contractions and a feeling of exhaustion in the extremities after a spasm, no constant subjective symp-

FIG. 2.—Position of Foot in Tetany.

toms are reported. The hands and feet are swollen, puffy, sometimes œdematous, covered with profuse perspiration, and respond as a rule to all tests of normal sensation. The tendon reflexes are sometimes normal, sometimes exaggerated or diminished, hence are valueless as diagnostic factors.

Besides these symptoms tetany offers a few phenomena which are commonly accepted as part and parcel of the disease, most prominent of which is Trousseau's sign. This consists in evoking an attack of tetany by applying pressure over the large nerve trunks or blood-vessels, the spasm continuing as long as pressure is exerted. In no other affection of the nervous system is this phenomenon observed, hence it is regarded as pathognomonic.

Chvostek's sign consists of an increased mechanical irritability of the motor nerves, especially well marked in the facial nerve. Slight pressure or friction over the trunk of this nerve at the ear will call forth active contractions of the facial muscles.

Erb found that an increased electrical reaction of the motor nerves was quite constant in all cases of tetany, especially when brought under the influence of the galvanic current.

Hoffman noted an increased electrical and mechanical reaction of the sensory nerves.

CASE I.—Alfred, the little son of Mrs. B—, had been up to his sixth month the type of perfect health, never having caused his parents the least anxiety or apprehension. The mother left the child on April 14, 1895, in its usual good health to make a short call on some neighbors, and found on returning home that hardly had she left when the child began to cry, the arms and legs became stiffened, swollen, and covered with perspiration. On trying to quiet the child by giving it playthings, she saw that the thumbs were pressed into the palms immovably, and on trying to move them caused the little one great pain. The feet and toes especially were also contracted and this condition lasted until April 19th, when the spasms disappeared. Four days later they reappeared, only in a more severe form, the child was moaning and crying day and night; the bowels, at first constipated, had be-

come loose and offensive, and the life of the baby was thought in danger.

On April 26, 1895, I was requested to see the case with the family physician, Dr. Briggs, and found the following condition:

The patient, a big, bouncing, healthy-looking boy, was sitting on his mother's lap crying piteously, with body bent forward, head reclining on the chest, arms flexed at the elbow, and legs drawn up. It was impossible to keep it in any position any length of time without seemingly great discomfort and pain. The child's face was swollen and the muscles of the lower part of the face were contracted, resembling the risus sardonicus as seen in paralysis agitans. The arms lay heavily at the sides, flexed at the elbow and wrist joints, the fingers flexed at the metacarpo-phalangeal joints and extended at the others. The thumbs were adducted and flexed beneath the fingers with such force that the palms were sore from the long-continued pressure. It was impossible to move the thumbs or fingers without calling forth pain and cries from the child. This position of the hands has been called by Trousseau the "accoucheur's hand" and is quite characteristic of tetany. The feet were extended at the ankle joints, the plantar surfaces inverted, forming a talipes equino-varus. The big toe was turned under the second and third toes, which in turn with the other toes were strongly flexed. The knees were extended and immobile, while the thighs were flexed on the pelvis.

The hands and feet were greatly swollen, but did not pit on pressure and were continuously covered with perspiration. The respiration was jerky and irregular, indicating involvement of the diaphragm. This was the condition of the child from April 26th to May 8th, the spasms being continuous without any appreciable intermission. At times it would laugh and play, would sleep well at night but very restless during the day, and ate sparingly of artificial foods. On several occasions much alarm was felt, especially at night when attacks of dyspnea would set in; these occurred usually when the bowels had not moved during the day or when the movement was offensive. Pressure applied over the brachial and ulnar nerves would invariably produce an exacerbation of the spasm and was vigorously objected to by the mother. From May 8, 1895, improvement began and continued until the contractions entirely disappeared, about May 20, 1895, and the child made a perfect recovery.

The treatment consisted of warm baths every four hours, and the administration of chloral and elixir of valerian.

The case is interesting not only as belonging to the continuous variety of tetany but because of its long duration and the severity of the contractions. These prevented me from examining for the phenomena of Chvostek, Erb, and Hoffman. These symptoms are most generally sought for in deciding a case of doubtful tetany but were uncalled for in this case.

The cause of the tetany was undoubtedly the intestinal derangements with the disturbances of dentition perhaps as an aggravating concomitant.

CASE II.—Child of George K.—, male, aged eighteen months; was first seen February 4, 1895, suffering with bronchitis and considerable gastric disturbance along with diarrhoea. On February 5th the hands and feet became "cramped," assuming the position described in Case I., for a few minutes, then they would relax. The interval lasted from one-half to two hours. The attacks would almost invariably set in when the bowels were about to move or when the child was picked up and its position changed. (Perhaps, in handling the child, pressure was applied over the nerve trunks in the arms.) This condition of things lasted one week and there has been no recurrence.

CASE III.—Child of Charles J. F.—, male, aged thirteen months; was first seen February 25, 1895, suffering as in the second case with bronchitis and stomach and bowel disturbance. Along with these disorders the hands and feet would "occasionally" contract spasmodically, remain so for five to ten minutes, then relax, without the patient losing consciousness. These spasms continued several times daily for six days. One slight attack was noticed about ten days after the disease was thought to have been cured.

CASE IV.—Child of John A.—, female, aged nine months, was first seen March 15, 1895, suffering with a severe bronchitis and tetanic spasms of both hands and feet. The attacks were of longer duration than in Cases II. and III., more severe, and the intervals shorter. This condition continued for three weeks when the child was discharged as cured. Four weeks afterward an acute meningitis set in and the patient died in six days. No recurrence of the tetany was reported during the meningeal disturbance.

CASE V.—Child of R. S.—, female, aged eleven months, was first seen April 16, 1895. This child was likewise suffering with a bronchitis (capillary), with severe gastro-intestinal disturbance, and had much difficulty with dentition. The tetanic spasms of the hands were of great severity, the thumbs were drawn forcibly into the palms, the index finger was extended, while the other fingers were firmly flexed over the thumb. The feet were not affected to the same degree, although the toes were partly flexed and the feet drawn into the equino-varus position. These spasms would never cease entirely but would pass into a state of greater contraction; then after an hour, relax somewhat. This child made a perfect recovery after two weeks' illness.

Dr. Briggs states that the sanitary surroundings were excellent in all cases except Case III. Cases I. and III. were nursed by the mothers who were healthy women, while Cases II., IV., and V. were bottle babies; Case II. being fed on cow's milk, Case IV. on goat's milk, and Case V. on some prepared food.

Dr. Briggs followed closely with me the course of Case I., and being an unusually acute observer and thorough clinician declares that Cases II. to V. were exactly similar to Case I., consequently I have no misgivings in believing that they were all cases of true tetany.

In a series of cases like this, some light is apt to be thrown upon the etiology and as they all occurred between February 4 and April 18, 1895, the natural inference would be that it was an epidemic. Such, however, is not the case, as they were separated by considerable distance and all existed prior to the doctor's first visit, except Case II., which was the first case observed. The bronchial disturbance was present in all cases, associated with some gastro-intestinal disorder and complicated with difficult dentition in Cases I. and V. As bronchial affections are of extremely frequent occurrence in Buffalo during the early spring and summer months owing to the cold, raw, icy winds from the lakes and the great amount of humidity in the atmosphere, this factor may be complacently set aside in the consideration of the causation of tetany, and there remains only the gastro-intestinal affection. That these disturbances do produce tetany is attested by all observers who have seen cases of infantile and even adult tetany. Whether these spasms are produced through reflex irritation or the absorption of ptomaines and central irritation will be difficult to decide. Cases are on record in which the attacks subsided after the expulsion of intestinal entozoa; also in which tetanic convulsions followed after the introduction of stomach tubes but where gastric disorders had previously existed. In children especially, tetany is frequently observed along with bowel

trouble and diarrhœa, particularly if they be also rachitic, and the affection is hardly ever observed in healthy children.

Besides gastro-intestinal disturbances there are many other recognized causative factors which favor the occurrence of tetany, such as the zymotic infectious diseases; certain toxic agents as alcohol, ergotin, chloroform; certain seasons as the months of February, March, April, and May; certain occupations, especially those of cobblers and tailors, and after thyroidectomy.

The symptoms and special phenomena of tetany along with the etiological factors would indicate an affection of no one particular part of the nervous system, but a process, toxæmic in character, affecting the whole nervous system, the cerebro-spinal as well as the ganglionic system. Just what the nature and specific character of this process is, must be for the present left open for speculation and for future theories until such time when by means of improved methods of examination its precise pathology can be determined.

INFECTIOUS VULVO-VAGINITIS IN CHILDREN.*

By ARISTIDES AGRAMONTE, M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT AT BELLEVUE HOSPITAL (O.D.P.), ASSISTANT IN THE SAME DEPARTMENT AT THE WEST SIDE GERMAN DISPENSARY.

THOSE of my readers who with preference give up the greater part of their time to the study of pediatrics, and who have opportunities for dispensary practice to any extent, will bear me out when I say that the condition considered in this paper is met with to-day in no less frequency than formerly, and if we are to be guided by the opinion of such men as Thomas,¹ Pozzi,² and other eminent gynecologists, vulvo-vaginitis at any age must be a disease of vastly greater transcendental importance than is generally believed.

This paper is based on clinical observations made upon thirty-two consecutive cases which occurred in my class at Bellevue Hospital Dispensary from March, 1894, to September, 1895. The greater number were in the summer months, and the ages ranged from five months to ten and a half years.

Etiology.—In view of the fact that the greatest men in the knowledge of venereal diseases are, at this late date, still at loggerheads regarding the specific virulence of the gonorrhœal pus, that the same state of affairs, difference of opinion, exists as to the identity of the gonococcus, and convinced that all kinds of pus are infective if not infectious, I have seldom lost time in a fruitless endeavor to find the source of infection in a given case in direct contact with a gonorrhœal male; yet, knowing that there is prevailing among the lower classes a belief to the effect that copulation or attempted coitus with a virgin child or young girl is a sure cure for all urethral inflammatory processes, I cannot but feel that the majority of cases not directly traceable to other active causes have been the victims of this infamous belief. On the other hand, we know that the healthy adult male organ, by repeated friction, may produce such an inflammation about the genitals of an otherwise healthy child as to later on superinduce a typical vulvo-vaginitis with all its accompanying symptoms; and this possibility we think ought to be borne in mind when dealing with medico-legal questions, as, for instance, when a child with severe vulvo-vaginitis justly accuses a man who on examination presents a perfectly healthy organ. There is a possible source of infection in the cloth-

ing, bedding, towels, etc., used by a gonorrhœic member of the family.³

Aside from the probable contact with a male, whether intromission takes place or not, among the frequent causes of vaginitis in children is the presence of oxyuris or even lumbricoides, or the introduction into the vagina of foreign bodies which becoming lodged in the pouch behind the hymen will induce repeated attacks of the acute condition without apparent cause; in this connection may be mentioned the accumulation of filth which is sometimes found in children of the poorer classes, who creep along the ground in the summer time, often without the proper covering to the parts.

Intertrigo and eczema induce scratching often so severe as to produce a vulvitis which easily extends to the vagina; the same may be said of the irritating secretions often met with in marasmic and badly nourished children, and also of the hyperacid urine which occurs in the sthenic fevers.

In children with enuresis, we have sometimes met a most aggravating condition, the result of the rubbing of the parts with the clothing saturated with the inevitably decomposing urine.

Besides the above, a short attack of vulvo-vaginitis has been known to occur as a sequel to the eruptive fevers.

In three remittent cases of vulvitis without apparent cause, we have found adherence of the nymphæ to the glans clitoridis and separated them with subsequent good results; but whether the pre-existing condition, by retaining smegma and secretions and thus irritating the parts, was the direct cause of the local inflammation I am not prepared to affirm on so limited an experience.

Pathology and Clinical Features.—As the title of this paper implies, it is not within its scope to treat of the simple form of catarrh of the vagina, which is always but a pathognomonic sign of great anæmia or other equally debilitating condition requiring no local treatment. It deals only with that state where there is an actual inflammation of the vulvo-vaginal tract with the production of abnormal discharges.

The gonococcus of Neisser has been found in company with other diplococci, in the discharges of infectious vulvo-vaginitis, for the differentiation of which great credit is undoubtedly due to the experiments of Dr. Henry Heiman,⁴ which most conclusively contradict the assertion made by Martin⁵ to the effect that it was impossible to separate them. On the other hand we find Neisser⁶ who says that vaginal flux is due to the gonococcus and that the usual vaginal secretions may contain all forms of bacteria except the gonococcus.

Certain conditions are always met with in vulvo-vaginitis, whether of gonorrhœal origin or not: such are the pronounced pyorrhœa consisting of desquamated epithelium and pus cells, large number of bacteria, strepto- and staphylococci, diplococci, etc., with its attendant mucus. Gonococci are absent in many cases. The external genitals are red, and on separating the œdematous labia, they may be seen covered with a foul-smelling discharge of greater or lesser consistency.

Abrasions and excoriations of the parts are common, and this, in connection with a stretching or tearing of the hymen, always makes us think that an attempt at coitus or actual masturbation has taken place. The inflammation of the external mucous membrane will extend for a longer or shorter distance into the vaginal canal, and in the great majority of cases will involve the urethra near the meatus. But few of such patients under our observation have failed to complain of pain on micturition, while only in two of them has the disease been allowed, through the evident in-

* Read before the Society for Medical Progress of the West Side German Dispensary, December 14, 1895.

difference and carelessness of the parents, to extend and involve the bladder walls.

Constitutional symptoms seldom accompany the above prominent local signs, and although a febrile movement may have been present in some of the cases I am inclined to think it more a sign of other inflammatory processes elsewhere, such as mild acute bronchitis, tonsillitis, indigestion, etc., so often present in children without any complaint being made to direct the mind of the attendant to them.

Treatment.—We believe that the number of remedies, external as well as internal, recommended for the relief of this condition is as great and heterogeneous as that put forth as valuable specifics in urethritis of the adult; like them, they have one after the other dropped into most righteous disuse; they have proved themselves useless, when not actually harmful, which they were in the majority of cases. Here we may mention solutions of acetate of zinc, nitrate of silver,⁶ bichloride of mercury,⁷ white oak bark, resorcin, red wine, matico, bismuth, grindelia,⁸ suppositories,⁹ etc., which have been used locally, and benzoic acid, bromide of potassium, pareira, etc., as internal medication; they are mentioned here only to most emphatically condemn them. The administration of drugs should be undertaken under absolutely no circumstances except it be directed to alkalinize the urine or rather lessen its acidity, which is very desirable where the urethra is involved or in cases of cystitis. Otherwise no medicine by the mouth may be expected to do any good, and when required as above suggested, only a mild diuretic like the citrate of potash should be used; almost any other remedy will only serve to derange the tender digestive apparatus and to throw further obstacles in the way of a rapid and permanent cure.

It is hardly necessary to say that in those cases where the vulvo-vaginitis is due to a remote cause or to a constitutional dyscrasia, treatment toward removing that cause or restoring the systemic tone must not be overlooked, as it will prove a most powerful ally in obtaining the final results.

Where there is rickets, phosphorus and cod-liver oil are indicated; where eczema of the parts is present, it is always difficult to tell which of the two conditions was the cause and which the result, because if it is true that eczema by inducing scratching may finally cause a vaginitis, it is none the less a fact that this condition is seldom unaccompanied by an eczema in the neighborhood of the genitals as a result of the irritating discharges from the latter.

Enuresis, which I place among the more frequent etiological factors in the production of vulvo-vaginitis, must be treated *per se*, which treatment we need not consider here. In all cases I would recommend a close scrutiny of the vulva, and where adhesions of the nymphæ to the clitoris exist they should always be torn and the parts kept well covered with vaseline for a few days after. It is a matter of common sense to remove any foreign body that may be present and to advise the most scrupulous cleanliness in all cases.

Whether the urethra be involved or not, my routine treatment has been directed to the vaginal canal and the external parts only; this consisted simply of flushing with a solution of permanganate of zinc or potassium (preferably of zinc), to the strength of 1-3,000.

The mother was instructed (the first time, practically taught) to insert into the vaginal canal, for a distance of one or two inches, accordingly a soft rubber tube of a thickness appropriate to the age of the child, the other end being connected with a fountain syringe or by siphon with an ordinary bottle; the reservoir being lifted one foot or eighteen inches only above the level of the table, the fluid is allowed to flow into the canal. The vulvar os is compressed at

short intervals to produce a distention of the vaginal walls and thereby allow the liquid to come in contact with every portion of the inflamed area, which it would not do otherwise, on account of the natural rugæ, more numerous and prominent in children than adults.

The reservoir is raised only to a height of one or two feet (higher as the child happens to be older), because in that way we obviate the possibility of forcing any of the solution into the cervical canal, while at the same time it is quite sufficient to produce enough pressure to distend any ordinary child's vagina to the required degree.

The soft rubber tube may be used with impunity on the most irascible child, and I have as yet to see any case where it has ruptured the hymen. An ordinary piece of soft drainage tubing should always be used, and never the closed end of a rubber catheter where the holes are placed on the sides. The two cases which came under our care with the complicating cystitis I did not trust to the parents for intravesical medication, but personally irrigated their bladders with a 1-6,000 solution of the same drug.

Were I to exclude from my statistics the two cases above mentioned which took respectively five weeks and two months to recover completely, the average length of time which the other consecutive thirty cases required was only of $12\frac{3}{5}$ days from the time of the onset, which in some few cases was even two weeks before treatment was applied for.

In conclusion I will say that, (I.) although vulvo-vaginitis, where other causes are not evident, is in many cases the result of direct contact with a gonorrhœic, it may also be the outcome of attempts at intercourse by a healthy male or masturbation; (II.) that in the majority of cases which come under observation there is no reason to suspect any immoral origin of the disease, while it may still be due to an innocent infection; (III.) that the local treatment of all cases should be as above described; the method is so simple and requires so little apparatus that it is within the reach of the most indigent as well as the most ignorant and stupid of parents; (IV.) that it should always be aided by constitutional treatment where the cause is not purely local; and finally (V.) that I feel convinced that, wherever tried, it will produce most satisfactory permanent results.

144 WEST SEVENTY-NINTH STREET.

Syphilitic Iritis.—Tuberculosis has its seat of development toward the adherent margin of the iris, is yellow, at times of rose tint, by reason of the development of a fine vascular network upon its surface; the condyloma, on the other hand, appears generally toward the free border, has a velvety appearance, and is brownish. Specific condylomata may, however, occur near either margin, may go through their evolution in a painless manner, may be accompanied by hypopyon, and may have a yellowish color at first, which afterward becomes brown. Treatment is begun by the subconjunctival injection of one division of the Pravaz syringe containing a 1 to 1,000 solution of sublimate.—Dr. SPÉVILLE, *Le Mercredi Méd.*, December 11, 1895.

AN EASY METHOD FOR REDUCING DISLOCATION OF THE HUMERUS IN ANY VARIETY OF THAT DISLOCATION.

By J. M. WARD, M.D.,

CORNELIA, N.Y.

EVERY physician and surgeon is aware of the usual manipulations for reducing this dislocation. The books figure the heel in the axilla and extension, the knee in the axilla, and some substitute a ball of yarn. Then there is the method by adduction, rotation outward, carrying the elbow on to the chest and the hand on the sound shoulder. All of them are painful and often fail, so that it is by repeated effort that success is gained. And finally there are the pulleys that look like a relic of the Inquisition. Forty years ago I adopted a new method that I have never seen de-

Progress of Medical Science.

The Aseptic Treatment of Abscesses and Suppurating Wounds.—The pendulum continues to swing backward, and antiseptics continue to be discarded on every hand. First the spray was abandoned; then the instruments were not immersed in antiseptic fluids; at about the same time antiseptic dressings began to be discarded; and, finally, antiseptic irrigations are being dispensed with. The past five years have seen antiseptics give place largely to asepsis. The question, Shall fresh wounds be treated with antiseptics? has been pretty generally answered, No; and a question which may now very properly be asked is, Shall infected wounds be disinfected? Zeidler, in making a negative reply to this question, calls attention to the work of Schimmelbusch, which proves

scribed. A boy in the year 1856 was thrown from a horse and suffered a dislocation of the humerus. I laid him on the floor, carried his arm up by the side of his head, held the scapula down with one hand, and pushed the head of the humerus into its place, which was easily done and with little pain. The movement of the arm completely surprised the muscles of the shoulder so that there was no contraction, and it lifted the head of the bone from its new locality. With that accomplished the reduction follows with hardly any of the audible snap that attends the common method. After reduction the arm is brought down to the side, and the head of the bone supported till the arm is at rest. I have treated every dislocation of the shoulder in the same way since that time. Persons standing around always remark as to how readily the reduction is effected. After carrying the arm up by the side of the head I sometimes give the hand to an assistant, then fix the scapula and draw it down with one hand, and elevate the head of the humerus with the other; chloroform is never needed.

that the value of disinfection is at least very questionable. Reichel and Hänel have arrived at the same conclusion, while, on the other hand, Henle and Messner found otherwise. More recent experiments seem to show that almost every sort of wound disinfection is contraindicated. Reichel made a number of experiments upon animals and found that he could best check extensive phlegmonous processes by free incision into the infiltrated tissue, and that a disinfection of the wound was of absolutely no advantage. During the course of the past two years he has treated a large number of cases of suppuration without any disinfection of the pus cavity. The pus was liberated by free incision, the cavity sponged out, and tightly tamponed with iodoform gauze. His results have been excellent. The aseptic treatment of suppuration is not new. The practice here, as is often the case, precedes the experiments. Säger, in 1888, limited antiseptics to simple suppurating wounds. In 1889, Zeidler wrote upon the treatment of suppurating wounds without the use of antiseptics. At that time he reported a hundred cases of all sorts of sup-

puration; and in 1892 he reported several hundred cases of suppuration, from granulating surfaces to extensive phlegmons, treated without antiseptics. In the same year Helferich appeared with a report of cases of phlegmon treated in the same way. In the recent handbooks of Schimmelbusch, Braatz, and Jaffé, irrigation with carbolic and bichloride solutions in suppurative processes is regarded as superfluous and harmful. Theoretically, it seems also to be recognized that not only in aseptic but also in infected wounds antisepsis is being replaced by asepsis. In practice this feeling is not entirely dominant. Many disciples of asepsis for clean operation wounds disinfect their suppurating wounds with antiseptic agents. For the benefit of these, Zeidler's experience and observation in a large number of cases may be briefly mentioned. In the Obuchoff Hospital in St. Petersburg, in the year 1892, 956 operations were done for abscesses, suppurative lymphadenitis, suppurative bursitis and tendosynovitis, parotitis, carbuncles, etc. In 1893, 1,165 similar operations were done; and in 1894, even more than this, including osteomyelitis, suppurative peritonitis, perityphlitis, and empyema. In these cases antiseptics were not employed. The operations were done in the following general way: The field of operation was prepared after the usual rules. During and after the operation the wound was simply sponged out with sterilized gauze. As a rule, irrigation was not used. When irrigation was resorted to, normal salt solution (0.6 per cent.) was employed. The wound was then very carefully and tightly packed with sterile gauze. Over this was placed a layer of gauze and then sterile wood-wool, moss, or other absorbent material. At dressings, the skin around the wound was cleaned with ether or benzin and the granulating wound irrigated with salt solution, dried, and dressed with sterile gauze. In most cases a dry gauze dressing is preferable. In some wounds of course a wet dressing is indicated. When this is necessary the gauze and cotton covering are simply moistened with salt solution. A large experience with parallel experiments has convinced Zeidler that it is the moisture of the dressing that is of benefit and not the antiseptic, as Reichel assumed. Zeidler has not been able to discover any difference between moist carbolic, bichloride, and salt dressings. There seemed to be some slight effect from the dressing of clay soaked with acetic acid, but this was probably due to the astringent effect of the same. He has never seen any advantage derived from dressing suppurating wounds with iodoform gauze. Numerous bacteriological investigations of suppurating wounds immediately after their disinfection have always shown pus cocci. With some few exceptions, Zeidler's experience with antiseptic dressings has been the same as that of Schlange. He has never seen an antiseptic dressing have any retarding or disinfecting effect upon the bacterial development. His results in the aseptic treatment of suppuration are throughout satisfactory, much better than are obtained with the energetic use of antiseptics; and his clinical observations corroborate the experiments made by Reichel upon animals. The local progress of the wound is better; the amount of secretion is less; and the development of granulations goes on normally, and the granulations do not become excessive or show the tendency to bleed that we are accustomed to see in wounds treated with iodoform gauze. Even when the dressing is not frequently changed—often being left on eight days—no strong odor is observed or any decomposition of the secretions. So long as a free escape of matter is provided for, the healing of the wound goes on normally; and it is claimed that there is much less reaction in the wound treated aseptically than when antiseptics are used. The important indi-

cations in the treatment of suppuration are free opening and free drainage; and in the opinion of Zeidler a disinfection of the wound is not only not indicated, but is dangerous. These observations from other sources suffice to illustrate the aseptic treatment of suppuration. In the treatment of the superficial suppurations of certain mucous surfaces the value of antiseptics seems to have been pretty well demonstrated. The resisting capacity of epithelial cells against chemical irritants is much greater than that of connective-tissue cells; and it is perfectly possible to apply to a mucous surface germ-destroying solutions which do not impair the vitality of the native cells. The conditions which exist here are so very different from those existing in a wound or abscess that these remarks have been confined to connective-tissue suppurations. By the antiseptic treatment we understand the use of antiseptics as they are ordinarily employed. The cauterization of wounds either by actual heat or by strong and corrosive chemicals is often a valuable surgical measure, but cannot in the usual sense of the word be included in antiseptic treatment. Nor should wounds which have recently been infected by rabies or anthrax or other virulent organisms be regarded in the same light as the ordinary suppurating wound. Suppuration is not a necessary symptom of the first class; and the latter must have needs been implanted many hours before suppuration is observed. It would seem that the ultimate use of antiseptics is to be confined largely to the destruction of bacteria outside of the animal body in order to prevent their admission therein. In the animal tissue bacteria are living cells lying against living animal cells of a very similar degree of vitality. Foreign agents which destroy one destroy the other; and it is very questionable whether an agent will ever be found capable of exercising a selective action upon the parasitic cells. In general therapeutics as well as in surgery there is a growing tendency to give the natural vital forces a chance to do what they can—a growing faith in the *vis medicatrix nature*.—*Annals of Surgery*.

The Pathology and Treatment of Gout—While the clinical picture of gout in its varied manifestations has been clearly made out and its treatment has been placed upon a fairly secure basis, a good deal of doubt and uncertainty surround its intimate pathology, and this the near future promises soon to dispel. In an address delivered recently before the Berlin Society for Internal Medicine, Klemperer reviewed the main phases through which this subject has passed, and presented evidence showing that none of the views hitherto propounded is entirely adequate or satisfactory. In addition he recited the results of some original investigations which, while not solving the problem, bring it closer to a solution and shed new light on an obscure subject. Garrod maintained that gout is due to increased formation and diminished elimination of uric acid; when an excess has accumulated in the blood it is deposited in the tissues, in which it gives rise to inflammation and necrosis. Recent investigations have, however, thrown doubt upon the accuracy of the results of Garrod's analyses. Nevertheless Ebstein admits the probability of an excessive production of uric acid, with accumulation in the blood; the circulating fluid, thus surcharged, causes local inflammation followed by necrosis, and in the necrotic tissues uric acid is deposited. v. Noorden has arrived at the conclusion that the gouty condition is independent of the presence of uric acid in the blood; the tissue-necrosis that occurs he ascribes to the activity of a hypothetic ferment, and he believes that the uric acid deposited locally is formed at the necrotic focus. To determine the relation between the presence of uric acid in the blood

and tissue-necrosis, Klemperer made a study of a number of individuals, including three persons in health, a case of leukæmia, one of pneumonia, two of interstitial nephritis (one compensated and one uræmic), and four of gout (three during a paroxysm and one uræmic). In all of the cases of gout, as well as in the case of leukæmia, and in both cases of nephritis comparatively large quantities of uric acid were found in the blood. To ascertain whether this result is due to increased production or to diminished elimination, the urine was studied in eight cases of gout, placed under like conditions. In two the daily amount of uric acid found in the urine was between 0.4 and 0.5 gram; in five between 0.5 and 1 gram; and in one between 1 and 1.2 grams. No relation existed between the amount of uric acid present in the urine and the character of the disease. It has been shown that the ingestion of thymus gland of the calf by healthy persons is followed by increased excretion of uric acid, and a similar increase was also found to take place in gouty persons. From all the facts it appears that there is no retention of uric acid in gout as long as the function of the kidneys is not materially interfered with, and that the presence of considerable amounts of this substance in the blood cannot be attributed to diminished elimination, but must be ascribed to increased production. The presence of similar amounts of uric acid in the blood of others than gouty patients, however, shows that this factor does not constitute the essential element in the causation of the gouty condition. Klemperer has found further that slight and insignificant differences exist in the solubility of uric acid in the blood-serum of gouty patients as compared with that of other patients and also of healthy persons, the solvent power of the serum in all being considerable—in fact, more than sufficient to dispose of the large amounts of uric acid present. He is, therefore, forced to the conclusion that the deposit of uric acid in the necrotic areas of gouty persons is not due to its insolubility in the blood, but is to be explained by the fact that such tissues possess a greater chemic affinity for uric acid than does the blood. Experimental observations showed also that while the blood underwent some diminution of alkalinity during the gouty paroxysm, this was not more than occurs under other conditions, and certainly not sufficient to account for the crystallizing out of uric acid. In view of all the evidence, the conclusion is reached that in the gouty certain unknown substances lead to inflammatory and necrotic processes in various tissues, and the necrotic tissues possess the property of attracting from the blood uric acid when present in considerable amount. These substances frequently develop from hereditary influences; sedentary pursuits and high living favor their formation; and two poisons in particular—alcohol and lead—predispose to their activity. It has hitherto been supposed that intoxication with lead paves the way for the development of gout by lessening the excretion of uric acid, but it has been shown that lead-poisoning does not have this effect; it may be that the lead present in the blood enhances the necrotic effect of the gouty poison. The practical deduction from what has gone before is that successful treatment must depend not upon increased solvent power of the blood upon uric acid, but upon the correction and the prevention of the necrotic process by increased oxidation and increased elimination. The attainment of these ends is largely reached through the employment of established measures whose use is sanctioned by the empiricism of centuries. These include increased physical activity, warm or hot baths, free ingestion of milk and of water, preferably alkaline, the avoidance of meat in excess, particularly red meat, and of fats, alcohol, and other carbohydrates. Finally, thy-

mus gland may be administered to increase elimination of uric acid.

Poisoning by Stale Eggs.—Dr. Cameron has reported the occurrence of vomiting and purging in seventy-four nuns and girl-pupils in the boarding-school attached to a convent in Limerick, following a dinner at which mutton and a custard composed of eggs, milk, corn-flour, and sugar were eaten. The corn-flour was suspected to contain arsenic, but analysis showed it to be free from poison of any kind, and to be of good quality. The sugar also proved to be pure. No other constituents of the meal could be obtained. The vomit and the stools were intensely green from the presence of biliary matter, but careful analysis failed to disclose the presence of ordinary poison. The viscera of two patients who had succumbed were also examined, but no poison was found. Ptomaines were found present, but in small quantity. The milk used had been boiled, and the meat was above suspicion. The eggs, however, were not fresh, and one presented a reddish-brown color and was thought to be bad. Some of the custard, given to pigs, induced severe diarrhœa.—*Dublin Medical Journal*.

Electric Currents of Extreme Frequency.—Drs. Apostoli and Berlioz report therapeutical effects of electric currents of extreme frequency, obtained by means of solenoids entirely surrounding the patient. Two series of experiments were made. The patients of the first series were hysterical subjects with various manifestations, persons suffering from neuralgia, etc. No result was obtained from electrization in such cases. In the second series of experiments, on the other hand, in cases of gout, arthritism, rheumatism, and glycosuria, the effect was remarkable. The condition of the patient was the first to be influenced. In addition, oxidation was invariably increased, as urinalysis showed. In three diabetic patients the glycosuria completely disappeared after twenty electrizations. Currents of extreme frequency are destined to become a powerful adjunct in the treatment of diseases due to impaired nutrition.—*Medical Standard*.

Tar Vapor-Bath in Psoriasis.—Dr. Wolf reports a case of generalized psoriasis of three years' duration in a twenty-year-old girl. The lesions generally were discrete, but on the buttocks, extensor surfaces of the upper and lower extremities they were confluent. The general outline was circular; there were no chains or gyrate figures. The whole vulva and the adjacent surfaces of the thighs were involved in one large scale area. There were small spots on the scalp, covered with white shining, papery scales. He put the girl immediately on Fowler's solution grt. iij., to be gradually increased, for internal treatment, and for local use he ordered her to take daily a vapor-bath of tar. A bath cabinet, of which there are a number on the market, and any will do, was procured; the patient sat on a stool within it, and under the stool was placed an alcohol lamp, with one ounce of pix liquida and four ounces of water in the small tin boiler with which the lamp was provided. Enough alcohol (one ounce) was put in the lamp to last fifteen minutes. The lamp being lit, the rubber flaps were tucked under the patient's throat and only the head allowed to protrude from the opening at the top of the cabinet, and the whole body was subjected for a quarter of an hour to the influence of the vapor. After coming out, the whole body was wiped dry of moisture and a little alcohol in the form of spirit of lavender rubbed in with the hands. The skin, very dry and harsh at first, now perspires readily, and is much softer and more pliant, and the patient is vastly benefited. Some of the patches have disappeared entirely, and the

large ones are looking much better. Of course, this method of treatment need find place only when the disease is so generalized as to put it beyond the rational employment of very stimulating applications in the form of ointments and pastes; and is not necessary in cases in which the patches are few and of small extent. Dr. Wolf has seen one death from pyrogallol in disseminated psoriasis, and much pain and misery caused by injudicious use of chrysarobin.—*Medical Standard*.

The Treatment of Pneumonia with Inhalations of Large Doses of Amyl Nitrite.—Dr. Hayem reports the employment of amyl nitrite in large doses by inhalation in the treatment of both pneumonia and pulmonary tuberculosis. The results were more favorable in the former than in the latter condition. Tuberculous patients can inhale the vapor from a suitable receptacle. Pneumonia patients used compresses upon which fifteen drops of the pure drug were dropped and the compress held close to the nose and mouth, deep inspirations being made the while. When this quantity has evaporated the amount is repeated again, and perhaps twice or even thrice. In this way fifty drops may be employed in the course of five hours. The physiologic phenomena of flushing, pulsation, pressure, respiratory and circulatory acceleration, cough, dyspnea, etc., soon disappear and leave no bad effects. The treatment is continuous throughout the illness and for a few days beyond defervescence. The dosage must depend upon individual tolerance. Other therapeutic measures are not contraindicated. It is not contended that amyl nitrite thus used shortens the duration of the disease or affects the temperature curve, although it mitigates the symptoms referable to the lungs. The effect is attributed to an influence upon the pulmonary circulation.—*Medical News*.

Insufflation of Sodium Chloride into the Nasal Cavity for Relief of Pain.—Dr. Capp recommends the insufflation, through an ordinary insufflator or other appropriate tube, of from two to four grains of pulverized table-salt, as a measure tending to give immediate relief in facial pain or headaches arising from trifacial irritation from decayed teeth, eye-strain, or from other causes such as ear affections, hysteria, or uterine reflexes. The measure was first applied, according to the author, by Leslie, and published in the *Edinburgh Medical Journal*, January, 1890; the latter had successfully employed it in the treatment of obstinate and long-standing cases, as well as acute neuralgia, headache, faceache, earache, toothache, and bronchial asthma. The application causes about the same temporary discomfort as would a pinch of snuff, but is not followed by bad results, and is usually successful.—*Texas Medical Journal*.

Hot Water Enemata for Periuterine Disease.—Dr. Reclus, of Paris, believes (*The Medical Week*) that the time is now past when apparently well-informed surgeons proposed and practised extirpation of the adnexa for the relief of pain on pressure in the vaginal culs-de-sac, ill-defined infiltration of the region, menstrual troubles, and a sensation of weight in the lumbar region. More than this is now required to justify laparotomy. To quote: "For my own part, I never operate in the presence of these affections of the true pelvis, before I have had recourse to a medical treatment in which hot-water enemata constitute the principal factor. The results obtained in this way are so satisfactory that in my wards at the Pitié Hospital we only operate on the average on one out of three patients admitted for undoubted oöphoro-salpingitis. Following the example of many of my col-

leagues, I begin by disinfecting the vagina and uterus, followed by dilatation of the cervix and prolonged drainage of the uterus, packing and, if necessary, curetting the uterine cavity, the walls of which I treat repeatedly with topical applications, such as tincture of iodine, creosote, and graduated solutions of zinc chloride. These manœuvres have been so often described that there is no necessity for repeating the description, except in so far as my method differs from that of other surgeons. Though it is not unusual to employ hot water, this water is not, as a rule, hot enough, the temperature ordinarily being from 40° to 45° C., whereas I use water of at least 50°, and still more frequently 55° C. The principal difference, however, is that, while other surgeons have recourse to vaginal irrigations, I employ enemata for this purpose. Not that I entirely disavise vaginal injections, were it only for cleansing the vagina, a result which is by no means to be despised; but it must be remembered that this is about all the benefit to be derived from such injections, which have little, if any, modifying effect on congestion of the uterus and its appendages. Their use rests on an anatomical error, for, if it is desired to reach the uterus, ovaries, and oviducts, the operations must be carried out through the rectum. An enema results in the accumulation of hot water in the ampulla of the rectum, into which the internal genital organs project. Enemata must, therefore, be resorted to under these conditions. It is better to take them in the morning, about half an hour before rising. The irrigator, filled with water at a minimum temperature of 55° C., is placed on the night-table, the cannula is introduced above the sphincter, and the tap is slowly opened, so that only a small quantity of liquid passes into the intestine, the slowness of the process preventing contraction of the muscular coat. In this manner, therefore, a much larger quantity of water can be introduced than if a strong jet be turned on at once. Should, nevertheless, a desire to defecate manifest itself, the water is shut off until this desire has passed, after which the tap is again slowly opened. The patient should retain the enema for half an hour if possible. Then she is allowed to evacuate the liquid, repeating the operation the next morning. By this antiseptic treatment, drainage of the uterus, and hot enemata, I have succeeded in relieving, and even curing, a large number of cases of perimetro-salpingitis. The infiltration of the culs-de-sac disappears, the peristaltic movements of the intestine break down the adhesions, and, instead of large masses filling up the true pelvis, the exudations and purulent collections are absorbed, the vaginal culs-de-sac become supple, the uterus movable, and the region in question resumes almost its normal condition, especially after judicious and moderate application of massage. I have on many occasions seen the tumor entirely disappear, and this result was in a large measure attributable to the use of hot water, which, as I have shown, is of the greatest value in surgery."

Osteomyelitis may be due to infection by the bacterium coli commune. Injected into the veins of the rabbit it produces inflammatory lesions of the osseous system resembling those produced by the usual organisms of suppuration. The lesions are usually multiple and most frequent near the epiphyses of long bones, especially at the lower extremity of the femur and upper portion of the tibia.—*Archives de Méd. Expér.*, May, 1895.

Hypertrophic Cirrhosis in children may not infrequently be associated with hypertrophy of the last phalanx of the fingers and deformity of the nail which is incurved and altered in structure.—GILBERT, *Sém. Méd.*

Therapeutic Hints.

Locomotor Ataxia.—"The early ocular palsies are of the greatest importance. A squint, ptosis, or Argyll-Robertson pupil may be the first symptom, and may exist with the loss only of the knee-jerk."—OSLER.

Neuralgia.—All cases of "neuralgia" of one side of the head, accompanied by inflammation of the eye, must be regarded with extreme suspicion; they are usually cases of iritis or glaucoma.

Favus.—

℞ Floris sulphuris	15 grms.
Sodii carbonatis	4 "
Picis liquidæ	50 "
Tincturæ iodi	50 "
Adipis	100 "

—*Rev. de Thérapie.*

Examination of Urine.—The addition, too, of a mineral acid to these acid specimens is a delicate matter; frequently, if more than a trace of nitric acid be added, we fail by producing too high a degree of artificial acidity to obtain the reaction; while other specimens require to produce precipitation the addition of an amount of nitric acid that is surprising and that would never be persevered in by an inexperienced person.—BRUNS.

Pulmonary Tuberculosis.—

℞ Calcium phosphate,	
Menthol	āā gr. iv.
Sodium bicarbonate	gr. iij.
Powder of nux vomica,	
Iron lactate	āā gr. ¼

M. To be taken four times a day with food.

—MARAGLIANO.

Sleep.—The chief advantage of sulfonal over trional is that the effect of a full dose continues longer and that it will produce sleep on the second night, and in a few cases even the third.

Chronic Diarrhœa and Dysentery.—

℞ Cupri sulphat.,	
Morphine sulphat	āā gr. i.
Quinine sulphat	gr. xxiv.

M. ft. pil. No. xii. Sig. One pill three times a day.

Granular Conjunctivitis.—

℞ Mercuric oxide	gr. iij.
Zinci,	
Thymol,	
Muriate of cocaine	āā gr. iss.
Camphor	gr. ss.
Vaseline	3 i.

M. ft. ung.

Drugs in Children.—In giving very active drugs to very young children it is generally best to write out the name and amount of the drug fully and not in figures, and to state at the top of the prescription that it is for a very young child and that the drops should be counted.—DANCHEZ.

Typhoid Fever. Diarrhœa is treated by withholding excessive quantities of food, and by the use of such remedies as bismuth salicylate, opium, etc. Overfeeding is largely responsible for tympanites. Oil of turpentine and oil of anise will usually relieve the distention.—KING.

Alcohol in Children.—The risk of alcoholism must always be considered in ordering alcohol for children, and where there is a history of alcoholism in a child's antecedents it is best to avoid it altogether. Dipsomania, generally hereditary, occurs both in boys and in girls, in the latter especially about the time of the first menstruation. Delirium tremens has been seen at five years old and cirrhosis of the liver, with definite history of abuse of alcohol, at three and one-half.—MOREAU.

Chilblains.—

℞ Resorcin	1 part.
Ichthyol	1 "
Tannic acid	1 "
Water	5 parts.

Externally!

The affected parts are painted with this liquid every evening, shaking the bottle well before using. When applied to the skin in this way, it is transformed in a few minutes into a dry layer of varnish. Under the influence of the resorcin, the skin shrivels up, and the chilblains rapidly disappear.—BOECK.

Morphinism.—Morphinism in the old is less disastrous than in early life. First, because the old seldom take the drug to excess—lessened care and work make it less necessary; second, and I take this to be the most important, the moderate use of opium after the age of threescore and five, is, in my opinion, salutary, distinctly conducive to length of days.—MAT-TISON.

Cardiac Disease.—For years past Glax has been accustomed to treat patients suffering from chronic diseases of the heart by diminishing the allowance of fluids, often to a considerable extent, and his results have been excellent. He gives the histories of a few such cases.—*Exchange.*

Exudative Erythema.—By exudative erythema is understood a disease of unknown etiology with polymorphic skin lesions—hyperæmia, edema, and hemorrhage—arthritis occasionally, and a variable number of visceral manifestations, of which the most important are gastro-intestinal crises, endocarditis, pericarditis, acute nephritis, and hemorrhage from the mucous surfaces.—OSLER.

Goitre.—In my experience removal of a patient with a growing or intractable goitre to a part of the country where the disease is less common has been followed by complete disappearance of the tumor, and some of my correspondents have had similar experience.—DOCK.

Nocturnal Enuresis.—Treat nocturnal enuresis by depressing the head and elevating the hips of the sleeping child. I have employed the method in some twelve cases in individuals of various ages and of both sexes with the best results.—STUMPF.

For the Relief of Stings of Insects.—

℞ Solution of ammonia	7 parts.
Collodion	3 "
Salicylic acid	0.3 parts.

—*American Journal of Pharmacy.*

Post-Partum Hemorrhage.—Post-partum hemorrhage has been treated successfully a number of times by saturating a piece of lint in turpentine and introducing it by the hand into the uterus. Contraction of the uterus soon took place, and the hemorrhage stopped. The remedy is quick and certain in its action, and easy of application. It produces no injurious result.—MAYNE.

Lassar's Paste.—

℞ Acid, salicyl	2.0 parts.
Vaselin	50.0 "
Zinc. oxid.,	
Amyl	āā 25.0 "

M.

Warts.—Flowers of sulphur, 150 grains; glycerin, 375 grains; pure acetic acid, 75 grains. Applications of this mixture should be made every day, and gradually the warts will become shriveled and dry and finally drop off. The mixture should be well shaken before it is used.—*Lyon Medical.*

Violent Urticaria.—Salicylate of soda in dose of twenty-four grains repeated every two hours for three doses.—LASSAR.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 11, 1896.

THE MISSING LINK AGAIN.

ONCE more the reporter has been helping the scientist out of a dilemma. As is well known—by those who depend upon the daily press for their scientific information—the only thing necessary to the absolute demonstration of the Darwinian theory was the discovery and production, living or dead, of the intermediate form between man and the anthropoid apes, popularly but incorrectly termed “The Missing Link.” And now it is said that he has been unearthed in Java, to the great joy of the newspaper biologist and the dismay of the orthodox.

The lucky explorer was a French surgeon attached to a Dutch regiment in the East Indies, who, some months ago, in digging for fossils, exhumed some fragments of a skeleton which struck him as something distinctly unusual. He therefore made a careful study of the bones and reported thereon to one of the Dutch scientific bodies. The discovery was accepted at once by the unscientific as conclusive, that the missing link was found and a great truth was established. But science spoke differently. Professor Cunningham, of Trinity College, Dublin, for the anatomists, and Professor Brinton, of the University of Pennsylvania, for the anthropologists, united in declaring, on the evidence of Dr. Dubois’ own memoir, that the remains described by him did not belong to any ape-like form at all, but were distinctly human, although prehistoric. They bore witness to the accuracy of Dr. Dubois’ report and to his evident scientific attainments, but thought that if he had had the opportunity of comparing his specimens with some of the human bones from the cave-deposits, he would have modified his opinion considerably. Indeed, as they might have reminded him, there are races of almost prehistoric character to-day in the same group of islands, the Dyaks, at Borneo, for example. Moreover, not so very far away is Ceylon, whose aborigines, the Veddahs, are still arboreal in their habits, living in flimsy huts built among the branches of trees, and whose series of assorted grunts hardly deserves the name of a language.

The whole episode beautifully illustrates the haziness, or rather fogginess, of popular ideas upon this subject. The common conception of the Darwinian theory, even among educated people, is roughly that man is assumed to be descended from a monkey, but that the mediate form through which the descent oc-

curred cannot be found, hence the theory cannot be proven and is probably baseless.

There are only three comments to be made on this statement. The first is that Darwin does not regard man as descended from a monkey. The second, that the missing link at this point is not one-fourth as great as at a dozen other places in the series. The third, that there is no “missing link” in the chain of pre-human descent, either here or anywhere else. From an evolutionist’s standpoint, it would be quite as correct to say that monkeys are descended from man, as man from monkeys. Both are from a common ancestor, but he was a long, long way back.

The ancestor of the primates probably diverged from other animals, not far from the very origin of the mammalia, and the ancestors of man and the apes began to diverge from him at least one hundred thousand years before any form like the present anthropoids on the one side or man on the other appeared. What has become of man’s immediate ancestors? He has simply exterminated them in winning his own foothold, just as the “Yankee” has the Algonquin. The more nearly alike are the needs and tastes of any two forms, the surer they are to fight to the death.

As to the second comment, even supposing that the present apes are the closest copies extant of our pre-human ancestor, the gap between us and them is insignificant by comparison with others in the series. Take that between plant and animal, for instance, or between fishes and snakes, or lizards and birds. Or, to come nearer, between whales and other mammals, or, previous to Marsh’s discovery, between the fox-sized eohippus and the modern horse.

The third position, that there is no missing link, is one which requires little defence before practising physicians.

To say nothing of the gill-clefts, the caudal developments, the pupillary membrane, the hairy coat, etc., which embryology reveals, have we not practical demonstrations of man’s kinship to the lower animals every day? What is that *appendix vermiformis*, which is causing us so much grief just now, but the shrivelled remains of a cæcum which was actually useful in the days when man’s forebears ate grass like the ox? What is hernia but the protrusion of intestine through a canal which in the quadrupedal position sloped upward, but now points downward on man assuming the erect position? What of those troublesome bodies, the tonsils, which an eminent laryngologist has recently declared “form no part of a normal throat”? They are simply lymphoid aggregations around the inner end of the second gill-cleft, and how far back does that take us? Back to the tadpole. The occurrence of the cleft in hare-lip at one or both sides of the premaxillary bone, instead of in the median line, is another “link,” and the rebellion of the lanugo hairs all over the surface at puberty, which causes acne, is another.

Even our disease processes are “reversions.” Calcareous degeneration is the process by which the oyster builds his shell; fatty, that by which the whale forms her milk; fibroid, that which enables the sponge-polyp to build his felt-like network. Lithæmia is at bottom

a reversion of our liver and muscle-cells to the avian or reptilian condition, so that they secrete uric acid and urates instead of urea. The menstrual periods still vibrate in a rhythm of weeks and lunar months, which echoes down from the time when our ancestors lay upon the sea-beach, and fed upon the flotsam and jetsam of the ocean surges.

To the physician, the pathologist, there is no "Missing Link."

MEDICINE AND SOCIETY.

ONE of the English reviews contains an article entitled "Medicine and Society," by Dr. J. Burney Yeo, which has attracted some attention, particularly among the more eager critics of the medical profession. Dr. Yeo's article aims in general to show that the present status of the medical profession, in relation to society, is not what it should be. Of course he takes up the subject of "specialism," portrays its familiar evils, and tells how, through the methods of specialists, the profession has become greatly degraded. He says that a man of very limited ability can now, in a short time, acquire a certain familiarity in the management of a single organ, and by merely identifying himself with its treatment, and compiling some work on the subject, however small its merit, be able to advertise himself as a skilful specialist and earn a large income. He adds, also, that specialists charge too large fees, and that society is beginning to resent it.

As regards these points, Dr. Yeo tells some measure of the truth, but he does not tell all of it. If it were entirely true that men of limited ability, by becoming specialists, could and did soon earn a large income, there would be at once an enormous rush of this class into the medical ranks, and society would be glutted with men of limited ability and unlimited charges, so that this evil would be bound soon to correct itself. As a matter of fact, it is probably doing so. We venture to say that, in New York at least, it is not possible for a man to enter a specialty and earn a large income, without a course of preparation involving from fifteen to twenty years, during a large part of which time he is barely earning his living. The large charges of which Dr. Yeo speaks are also somewhat illusory things; at least we venture to say that the young specialists of the country are not, as a rule, earning any extravagant incomes, and we hear of many of them who charge only ordinary office fees for doing their special work. We are not at all blind to the evils of which Dr. Yeo speaks, but it does not follow that medicine is going to the dogs because there are some imperfections in the medical system. The practice of young men passing at once from the college and the hospital into a narrow specialty is to be very greatly deprecated, and we have never ceased to call attention to this particular defect.

Another trouble that distresses the English critic is the etiquette which controls medical practitioners. The evils which are discussed by the doctor in connection with this point exist more, however, in English practice than in American, judging from the special

criticism Dr. Yeo makes. He says that physicians claim the right to name the doctor who shall be called in consultation, and that the patient has nothing to say upon the subject. This is certainly not now the case in America where, as a rule, the wishes of the family are always consulted, and in the happy State of New York the preference for any practitioner duly qualified, is treated with courtesy and attention.

Thirdly and lastly, Dr. Yeo brings up the burning question of unprofessional advertising. Here, too, we think that Dr. Yeo is distressed by facts that may justly disturb English society, but certainly do not very much affect our own. If the name of an English physician by any chance gets into the paper, even though it be a most modest statement with regard to a domestic change or a personal characteristic, the medical press at once arises in its wrath. We quite agree with Dr. Yeo that there is an enormous amount of humbug in this matter.

The MEDICAL RECORD has always taken the ground that the physician has no right to exploit his own skill and greatness, or to advertise the same in the public press, on the broad ground that by so doing he appeals to an audience which is not so capable of critically judging such matters as it is with regard to the pretensions of a seller of dry goods or soap. If, however, society is interested in the fact that a prominent lawyer or a prominent physician has moved to another city, or is going into another country, or if this physician can say something, without advertising his own skill, regarding a matter of public interest, it is proper and right that he should do so. Dr. Yeo, however, seems to go further, and think that medical men have a right to advertise just as a tradesman does, and he undertakes a very false line of reasoning in defence of this view. Medical men, he says, advertise themselves in medical journals, by their articles, through their books, the instruments that they devise, and their teaching. But this, we contend, is very different from appealing to a lay audience which has not the capacity to judge of the merits of the advertiser. If a man writes an article to advertise himself in a medical journal, and his article is weak and pointless or if it is boastful and untruthful in statement, ten thousand eager eyes are quick to detect it and to criticise the author. On the whole, it seems to us that Dr. Yeo has not done himself or the profession much credit by his article. If it were written by him to advertise himself, he has succeeded, but advertisement is not an unmixed good.

ERYSIPELAS AND THE SIR ANDREW CLARKE MEMORIAL.

THE London Hospital has abandoned the idea of erecting an "erysipelas ward" for women and an "isolation ward," in memory of the late Sir Andrew Clarke. We are glad to hear it. To perpetuate the memory of any man by building an erysipelas ward and an isolation ward shows a tremendous non-appreciation of the eternal fitness of things. Sir Andrew Clarke, as far as we know, never had erysipelas.

never wrote about it, and never contributed anything in elucidation of its pathology or in elaboration of its treatment. Sir Andrew Clarke was, furthermore, so far as we have been able to learn, never "isolated," never wanted to be isolated, and never took any practical interest in "isolation wards." We bid good-bye, with pleasure, therefore, to the erysipelas and isolation memorial business of the great London Hospital. We understand that it is proposed to build a new wing to the hospital which shall be called the "Clarke Memorial Wing." We wish there were a better word than "wing" to associate with the memorial, but wings are, at least, better things to associate with those who are gone than the memorial perpetuation of any disease that may secure them.

SEPTIC TONSILLITIS.

UNDER the above title, Dr. Stewart A. Tidey, of London, describes a malady which he thinks is specific in its origin and course. He says that his experience, accumulated during several years of hotel practice in Switzerland, has led him to believe that "septic tonsillitis," as he calls it, is an acute specific disease, having as much definiteness in its symptoms, course, and origin as has scarlet fever or measles.

It is a pleasure to find that hotel doctors have been utilizing their experience for the benefit of science, and we take much satisfaction in encouraging clinical observations at hotels by giving some details of Dr. Tidey's specific disease. It is a trouble, he says, which occurs with great frequency at and after the most crowded seasons, when the air near the closets is very offensive, and he says that the disease is frequent in inverse ratio to the sanitary provisions of the hotels. The disease is known at Geneva as the "white throat of the lake." Dr. Tidey is confident that it is directly transferable from person to person, and that such a mode of origin is favored by overcrowding and bad ventilation. The trouble begins with pain at the seat of inoculation, generally one tonsil. It rapidly involves the whole throat, causing dysphagia. The pain is often accompanied by pricking and burning in the soft palate. The patient suffers from headache, pain in the back and limbs, prostration, and constipation. Sometimes there is a chill, and always considerable fever. There is enlargement of one or both tonsils, inflammation of the soft palate, and extension of the inflammation into the naso-pharynx. At first, the throat is uniformly bright red in color. There is rapid ulceration over the tonsils, causing white patches of greater or less extent, which involve the pillars of the fauces and soft palate. There is a copious secretion of mucus and muco-pus. The disease lasts five or six days. Treatment consists in systematic cleansing of the throat by the application of glycerin and carbolic acid or of glycerin and tannin. Internally, laxatives and tonics are given.

No bacteriological study of this alleged specific malady has been made by Dr. Tidey, and he does not even seem to have investigated the literature on the

subject. Otherwise, we think that his "Switzerland sore throat" does not differ very much from the mixed infective sore throats that are common in all parts of the world.

ARTIFICIAL ABORTION.

A PROMINENT specialist in this city, Dr. Garrigues, begins an article on "Artificial Abortion" in this way (*American Gynecological and Obstetrical Journal*):

"To judge by the very frequent applications I receive from women, married not less than unmarried for interruption of early pregnancy and the wonderful *sans gêne* with which the request is made, as well as by the coroner cases reported in the public papers, I am inclined to think that this operation is being performed quite frequently and without scientific indications."

The writer adds with *naïveté*:

"Personally I have hurt my business interests very considerably by constantly refusing to perform this operation, except when it was called for on strictly scientific grounds, not only in my mind, but according to the opinion of other competent and sometimes superiorly able judges."

He then proceeds to give a description of the proper indications for abortion and the technique of its performance. Pelvic deformities, serious disease of the mother, such as tuberculosis, cardiac trouble, aneurism, chronic nephritis, carcinoma, threatened insanity, or serious nervous disease furnish legitimate indications for the operation. If indications point to the great certainty that the fœtus may inherit tuberculosis, cancer, or syphilis, Dr. Garrigues thinks that it may be destroyed. Here, however, serious deliberation must always be required. The advice is given never to induce an abortion without having a formal consultation. The result of this should be put in writing and signed; the written consent of the husband, if there be one, and of the patient should be obtained.

The technique of the operation for abortion is given in detail, and it shows how different the approved, safe, and scientific procedure is from that adopted by the charlatan. The patient must be anæsthetized, the vagina, vulva, and nearest part of the outer surface are disinfected as for childbirth or a gynecological operation. The cervical canal is dilated by means of coniform hard-rubber or expanding steel dilators until there is room enough at least for a curette, but if possible for a finger besides. Not only the fœtus and the ovum but the spongy endometrium should be removed, the latter forming a mass that easily bleeds and has to become disintegrated and to be expelled. It is therefore better to remove it at once. Before scraping one should wash out the uterus with creolin, and after having finished scraping, a quart of a one-per-cent. solution of this drug is run through the cavity.

A 50,000-Franc-Prize has been awarded by *L'Académie des Sciences* (Prix Alberto Lévy) to Drs. Roux and Behring for the discovery of an efficacious treatment of diphtheria.

News of the Week.

A New Swindler.—A tall man, with dark steel-gray hair and beard, of pleasant address, representing himself as an officer of "the American Union Insurance Company," calls on a clergyman, asking the address of a good doctor in the neighborhood; he next visits a physician and explains that he wishes to insure him for \$2,000 and make him an examiner. He has heard a good report from such a clergyman, Mr. So and So. The physician, who becomes easily entrapped, pays \$3 for an application, the agent promising to send a physician to examine him, and thus endeth the lesson.

Dr. James E. Reeves, of Chattanooga, Tenn., died on January 4th, at the age of sixty-seven years, after a short illness. He was a Trustee of the American Medical Association and the author of a "Manual of Medical Microscopy for Students, Physicians, and Surgeons." He had at different times held numerous important public positions, both within and without the medical profession, and was highly esteemed for his admirable personal qualities and his varied professional attainments.

The Camden (N. J.) City Medical Society held its annual meeting on January 1st. Dr. O. W. Braymer, the retiring President, read an interesting paper on "The Relation of the Medical Profession to the Public Schools." The following officers were elected: *President*, Dr. W. S. Jones; *Vice-President*, Dr. W. R. Powell; *Secretary*, Dr. J. S. Nicholson; *Treasurer*, Dr. W. W. Kain; *Historian*, Dr. D. S. Strock; *Librarian*, Dr. S. G. Bushey; *Managers of the Camden City Dispensary*, Dr. H. Genet Taylor, Dr. Alexander Mecray, Dr. E. L. B. Godfrey, Dr. O. R. Gross, Dr. Joseph W. Wills, Dr. O. W. Braymer, Dr. J. G. Doron, and Dr. W. A. Davis.

One of the Advantages of Being Married.—The women of the State of Missouri are circulating a petition to the Governor of the State, requesting that he appoint only married men as resident physicians at the various insane asylums in the State. This is a most extraordinary reflection on the character of the assistant physicians of the Missouri State Asylums. We feel sure that the Governor will not do so silly a thing as to grant the petition.

Careless Prescribing.—A physician of this city prescribed morphine for a patient whom he had not seen, and on account of a misunderstanding with the messenger directed a full dose for an infant, promptly causing its death. The case goes to the coroner.

Privileged Communications by Physicians.—The Court of Appeals in this State has decided in a recent case of damages for railroad injury that when one of two or more physicians in attendance offers testimony, the others of different opinions cannot be restrained from doing likewise on any plea that they would be violating the confidence of the patient. In other words, all the medical attendants are on an equal footing as regards privileged testimony.

Bovine Tuberculosis at the Norristown Hospital for the Insane.—The Norristown Hospital for the Insane is threatened with another outbreak of tuberculosis among the cattle on the hospital farm, notwithstanding the experience last year, when a large herd of tuberculous cows was killed off in the hope of stamping out the disease. At the monthly meeting of the Trustees on January 3d, it was reported by the steward that last month seven cows were killed for beef, one of which showed symptoms of a well-developed case of tuberculosis. Since then other cows in the herd have been subjected to the usual test, but no other victims were found. It was discovered recently that under a section of the by-laws governing the institution the Trustees were authorized to appoint a committee of physicians. Since then President Stinson named as the committee Dr. S. Weir Mitchell, Dr. H. C. Wood, Dr. C. K. Mills, and Dr. Anna Bromall, of Philadelphia, but these all declined the appointment. A further endeavor will, however, be made to persuade them to accept. They are not expected to assume any direct responsibility, and are intended to be called in consultation only when an extraordinary case presents itself.

The Inter-County (Pa.) Medical Society held a meeting at Spring City on January 2d, and, among other business, elected the following officers: *President*, Dr. F. W. Heckle, Spring City; *Vice-Presidents*, Dr. William Brower, Spring City; Dr. W. Marsteller, Phoenixville; *Recording Secretary*, Dr. J. S. Morey, Royersford; *Corresponding Secretary*, Dr. Burns, Royersford; *Treasurer*, Dr. Finkbeiner, of Parker Ford.

A Medical Man by the Name of Dr. Jameson has been making quite a stir in South Africa. According to the last reports, it looks as though the shoemaker should have stuck to his last.

Political Places for Physicians.—The recent political upheaval in Maryland has caused wideawake statesmen to survey the field in search of spoils, and the *Maryland Medical Journal* gives a list of the particular spoils to which competent medical men are eligible. In Baltimore alone, there are 30 places, with salaries ranging from \$400 to \$3,000.

Journalistic Change.—The *College and Clinical Record* will hereafter be known under the name of *Dunglinson's College and Clinical Record*.

Improvements for the City Hospitals.—Corporation Counsel F. H. Scott has prepared a bill entitled, "An act to make further provision for the maintenance, care, and treatment of sick, infirm and destitute persons under the jurisdiction and care of the Commissioners of Public Charities in the City of New York." The bill provides for the erection of new buildings, and repairs and alterations to existing buildings; also for the construction upon Blackwell's Island of an electric lighting plant of sufficient size and capacity to light all the public buildings on said island, and to introduce electric lights into all the buildings.

The Rush Monument Fund has now reached the sum of \$3,548.39.

Mortality in November.—The bulletin of the State Board of Health for the month of November says that during the month there were 200 more deaths than in November, 1894. The death-rate per 1,000 of population was 15.50. The infant mortality (under five years of age) was 27.4 per cent., which is the same as that of the corresponding period for the last two years, that of October having been 31.5. The zymotic mortality has decreased from 16.7 per cent. of the total deaths to 13.5, and is below the average for this month. Compared with last November the deaths from diphtheria are much less, being 5.8 per cent. of the total, against 8.5; there has been a smaller increase than usual since October. From other zymotic diseases the mortality is almost identical with that of a year ago, except from measles, which shows a marked increase, and to a less degree from typhoid fever and malarial diseases. There were 96 deaths from measles, which is double the number reported in October. It has been especially prevalent in New York, Brooklyn, and Albany, in which 74 of the deaths occurred. From typhoid fever there were in the five cities of over 100,000 population 2.4 deaths per 100,000 population; in the rest of the State there were 4.0. From diphtheria there were 9.0 deaths per 100,000 population in these large cities; in the rest of the State there were 5.0. There were 17.2 deaths per 100,000 population in the large cities from consumption, against 12.0 in the rest of the State. Deaths from acute respiratory diseases were nearly double the number occurring in October, though not above the average for this month.

New York Academy of Medicine.—The following officers were elected at the meeting on January 2d: *Vice-President*, Dr. Egbert H. Grandin; *Trustee*, Dr. Joseph E. Janvrin; *Members of Committee on Library*, Dr. Herman L. Collyer and Dr. B. Farquhar Curtis; *Member of Committee on Admission*, Dr. Robert A. Murray; *Delegates to the Medical Society of the State of New York*, Dr. William S. Gottheil, Dr. Reginald H. Sayre, Dr. Ralph L. Parsons, and Dr. Charles H. Richardson. As a result of the vote on candidates for resident fellowship, the following were declared elected: Dr. Frank J. Blodgett, Dr. George T. Hunter, Dr. George W. Smallwood, and Dr. F. C. Valentine. Dr. Richard P. Francis, of Montclair, N. J., was elected to non-resident fellowship.

A Criminologist Sued.—Dr. Aubry, a Brest physician, is the author of two works called "A Family of Criminals" and "The Contagion of Crime." In these he instanced a family, whose name he gave, the members of which had incurred a number of convictions for various offences during a period of something like seventy years past. He added that one of the female members of the family had led a dissolute life in Paris, and that after living upon the debauchery of others, she had retired on a handsome competence. This woman, being still alive, brought an action for libel against the doctor. It does not seem to have been denied that the facts were as stated in the books, but the court held that the author was not justified in raking them up. At the same time, as it was held

that he had no intention to annoy, but had been actuated solely by scientific considerations, the judge has let him off on paying his own costs and those of the plaintiff.

The Dissection of a Famous Monarch.—The *Lancet* gives the following interesting and suggestive account of the post-mortem examination performed upon William III. of England:

Report of the Physicians and Surgeons, commanded to assist at the dissection of the Body of the late King.

Upon the first view of the Body, before dissection, the following appearances were remarkable.

The Body in general was much emaciated; Both the Legs up to the Knees and a little higher, as also the right hand and arm as far as the Elbow, were considerably swelled.

There appeared likewise on the left thigh near the Hip, a bladder full of water, of the bignesse of a small Pullet's Egg, resembling a Blane.

Upon opening the Belly, the Guts appeared of a Livid colour, and the blood contained in the vessels there of blackish: The gutt called Jlion had in some places, the markes of a slight Inflammation.

The Pancreas, Mesentery, Liver, Gall, Bladder, Spleen, Kidneys and Stomack, were all sound and without fault.

In the Thorax or Chest wee observed, that the right side of the Lobes of the Lungs adhered to the Pleura, and the Left, much more, from which upon separation there issued forth a quantitie of Liquor judged to be purulent or frothy serum: The upper Lobe of the left side of the Lungs and the part of the Pleura annex to it, were inflamed to a degree of mortification: And this wee looke upon as the immediate cause of the King's death.

from the ventricles of the Heart and the great blood vessels issuing out of them were taken severall large tough fleshylike substances of the Kind called Polliposer.

The Heart was of the smaller size, but firm and strong.

Upon laying bare the right Collar bone, wee found that it had bin broken neare the shoulder and well sett, some Extravasated blood was lodged above and below the fracture.

The Brain was perfectly sound and without any signe of distemper.

It is very rare to find a Body, with so little blood, as was seen in this, there being more in the Lungs, than in all the parts besides putt together.

Signed	HUTTON	BLONEMORE
	MILLINGTON	BIDLOO
	[and others.]	

Delivered to ye Queen and Councell, March 11th, 170½. Endorced—"Dissection of the Late King's Body." In writing of a later date and in different coloured ink, similar to the signatures—"To his Grace the Duck off Queensbury, &c., &c."

Paris has 521 foreign medical men among the total 2,922 in the city. It is supposed that New York has more than 600 native American medical men among its 3,000 practitioners.

Japan appreciates the work done by physicians. A statue has recently been erected at Tokio of the late Dr. Müller, the first German Professor at the Tokio Medical College.

An Industrious Scientist and Physician.—Dr. Haffkine recently delivered an address in London on his work in vaccinating against cholera in India. His work lasted twenty-nine months; 70,000 injections were made, on 42,179 individuals, without a single mishap.

The Twelfth International Medical Congress.—The date of the Twelfth International Medical Congress, to be held in Moscow, has now been definitively fixed for the week August 19–26, 1897—cholera and the state of the political atmosphere permitting. The Czar has signed the Imperial Rescript sanctioning the congress, and His Majesty's uncle, the Grand Duke Sergi, Governor-General of Moscow, has consented to be its patron. The President will probably be Professor Klein, Dean of the Medical Faculty of Moscow University; Professor Erisman, Professor of Hygiene in the same University, will be General Secretary. The Russian Government has granted a subvention of 120,000 francs toward the expenses of the congress. The official languages of the congress will be French and German.

Medical Students in Revolt.—There has been trouble in the Medical University at Athens, and also in that at Moscow. At Athens, the students were dissatisfied because five female students had been admitted to the Attic University. The students were divided in opinion as to the propriety of this, and matters came to a crisis in the chemical laboratory one day when a student from Arcadia shot another from Asia Minor. At Moscow, the trouble arose from the unpopularity of Professor Zakharin, because, it was said, he was a court physician. This is an old offence, however, and there was probably something more behind it. The professor's lectures were boycotted by the students, but he has continued to lecture in spite of diminished audiences.

Another University Admits Women to its Medical School.—The Government of Hungary has issued a decree to the Universities of Buda-Pesth and Klausenburg, ordaining that women shall be admitted to academic studies, and also to the special studies which will equip them to be physicians for women and children, teachers, and so on.

The Hospital Hold-up will not be condemned by the Academy of Medicine. By a vote of 108 against 47 this body will refrain from memorializing the Mayor upon the subject.

One Reason why no physician's name appears upon the Board of Charities may be inferred from the remarks of Dr. Girdner at the Academy meeting. This gentleman stated that he had been advanced as a candidate for the commissionership by members of the faculties, who had then opposed him when they found him unwilling to promise to uphold the action of Mr. Porter, the gentleman who has since been deposed.

The Jefferson Medical College has purchased additional land and will in the course of next year build a laboratory, five stories in height and fitted with all modern apparatus, the first floor to be used for a dispensary. The Medico-Chirurgical College has also purchased more land and is putting up a new amphitheatre.

An Epileptic Colony, which is known as the Passmore-Edwards House, has recently been established in England by the National Society for the Employment of Epileptics. It is estimated that there are between thirty thousand and forty thousand epileptics in England.

A Tri-State Medical Society Becomes Bi-State.—We never knew exactly why the larger medical organizations of the West were so constantly bred in triplets, but this has been the popular method of combined State organization, and there are now more tri-State medical societies than we can keep in mind. One of them has, however, temporarily come to grief, the Tri-State Medical Society of Missouri, Illinois, and Iowa. At its meeting on October 1st, 2d, and 3d, at Des Moines, there were delegations from Missouri and Illinois, but Iowa itself was not represented. The trouble, as explained by *The Iowa Medical Journal*, is that the Tri-State Society has an official organ which has published statements derogatory to the medical profession of Iowa, and of Polk County in particular, where the Tri-State Society held its last meeting. The result was that the Polk County doctors did not join in the gathering, and the tri-State society was really a bi-State society. Arrangements are being made, however, to have all the difficulty readjusted.

A New Society in St. Louis.—The St. Louis Academy of Medical and Surgical Sciences was recently organized by thirty-five physicians of that city. The following officers were elected: *President*, Dr. George W. Cale, Jr.; *First Vice-President*, Dr. James Moores Ball; *Second Vice-President*, Dr. Arthur E. Mink; *Secretary*, Dr. Emery Lamphear; *Treasurer*, Dr. Willington Adams; *Orator*, Dr. Thomas O. Summers; *Curator*, Dr. George I. Thompson. Among those present at the organization of the academy were Dr. Walbridge, brother of Mayor Walbridge, Dr. Walter Dorset, Dr. Given Campbell, Dr. F. P. Norberry, and Dr. G. F. Hulbert. The organizers of the new society are unanimous in saying that ethics will not enter into the purposes of the organization. The membership is limited to fifty.

Vital Statistics of Massachusetts.—The Twenty-sixth Annual Report of the State Board of Health shows that during the year ending June, 1894, the birth-rate was 27.55 per thousand and the death-rate 20.13 per thousand. It is seen from the report that, among other interesting changes, there has been a steady reduction in the annual number of deaths from typhoid fever.

The Mary Thompson Hospital of Chicago for Women and Children.—Dr. Marie J. Mergler, Professor of Gynecology and Clinical Gynecology, North-

western University Woman's Medical School, has been appointed gynecologist and head physician and surgeon to fill the vacancy caused by the death of Dr. Mary Harris Thompson. In memory of the valued services of the deceased physician the name of the hospital has been changed from "The Chicago Hospital for Women and Children" to the above.

Royalty's Physicians.—To the Czar, Dr. Zakharin; to King Humbert of Italy, Dr. Saghone; to Emperor William, Dr. Bergmann; to Queen Victoria, Sir William Broadbent; to the Emperor of Austria, Dr. Von Widerhofer; to the Mikado, Dr. Kitasato.

Interest in the Missing Link has been revived by the fact that Dr. DuBois, who is the discoverer, has been lecturing and showing his treasures in England. The first criticisms of Dr. DuBois' findings were adverse to the claims that he set up, but since he has brought his specimens to European centres, where they have been examined, there seems to be more credence placed in their importance. He has, at any rate, found the remains of a skull of which the cranial capacity is only about one thousand cubic centimetres. This is a much smaller capacity than that of the average human skull (1,500 c.cm.) and is about twice as large as that of the male gorilla (531). However, the skulls of human microcephali have a capacity of only 419 to 440, and a skull of 1,000 centimetres is considered as only semi-microcephalic, so that the volume alone would indicate little. The skull discovered by Dr. DuBois has other peculiarities, resembling those of the Neanderthal type. The frontal region is very low and flat, and the glabella and supra-orbital ridges are enormously developed. There is also a distinct ridge extending from the curved line of the occiput to the temporal region, which is characteristic of apes and absent in man. Altogether, Dr. DuBois' findings are, at least, deserving of the very great interest they have excited.

The Infectiousness of Suicide has been well shown by some cases that occurred recently in St. Petersburg. During the month of September three young girls threw themselves from high windows on to the pavement, intending to kill themselves. One threw herself from the third story, another from the fourth, and one from the fifth story; all recovered from their injuries.

An African Medical Explorer.—*The British Medical Journal* says that among the feats which have heretofore baffled the efforts of travellers is the exploration of Lake Rudolf. A young American man, Dr. Donaldson Smith, has, however, succeeded in reaching this lake from the north. He is thus the first white man who has visited this region. He left London last May and started with a taxidermist and another companion.

Some Recent Experiences with Antitoxins.—Dr. James Swain, of Bristol, publishes in the *British Medical Journal* the report of a case of malignant tumor, an osteosarcoma of the upper jaw, treated by the mixed toxins of erysipelas and B. prodigiosus. The result was a failure, but, according to Coley, the

osteosarcomata are least benefited by this mode of treatment. In the same journal, Dr. Frances Heatherley reports a case of cellulitis treated by an anti-streptococcic serum. The serum was obtained from the Pasteur Institute. The patient was not affected by the injections, and subsequently died; treatment was not begun until a late stage of the disease. Mr. E. A. Steele, in the same issue, reports a case of erysipelas neonatorum, treated by injections of antistreptococcic serum. The child was three weeks old, and three injections were given. Dr. Steele says that in his practice he has seen a number of cases of erysipelas neonatorum, but had never seen one recover when the disease was so far advanced as in this case, and he is convinced that the child's recovery was due to the serum.

Medical Fees in Austria.—The country practitioners in Austria complain that the fees which they receive are too small, and one of them has proposed the following scale (the equivalents being given in American money): Office visit, 15c.; first visit to a patient's house, 30c., subsequent visits, 25c. each; night calls, 60c.; setting a fracture, \$2.25; major surgical operations, such as amputations and the like, from \$6 to \$9; hypodermic injection 20c.; antitoxin injection, 80c.; bacterioscopic examination, 80c. The prizes of the profession do not seem to lie in Austria.

Short Men and Fat.—A man named Clark, who advertised to make short people tall and fat ones thin, has recently disappeared from his Twenty-third Street office, presumably returning to London, whence he came, and many short men find themselves even shorter than before meeting him, while the fat ones are at least not putting on much flesh, while they can no longer laugh. When he promised the short ones they would grow, he probably meant to grow wise by experience, which process they are now going through, while he is spending the fees paid in advance.

Medical Annuals.—The time was when semi-annual and annual retrospects and summaries, under various names, of the work of the year had their use and value; but in these days of live medical journals, ably edited, unceasingly scouring the world for items of interest, eager to record everything novel both in theory and practice, with exchange lists exceeding in number and variety anything which might be collected in any other way, it would surely seem the medical profession might safely rely upon them, with their voluminous and complete indices, as the most reliable records of each year's work and progress, and more wisely and profitably invest the money which has heretofore been spent upon abstracts, retrospects, and annuals of all kinds, in one or more first-class weekly and monthly medical journals.

Puerperal Fever and Puerperal Infection.—*The University Medical Magazine* makes a plea for a more correct nomenclature with reference to the term "puerperal fever." It asserts that this term, "puerperal fever," may include any form of febrile disorder occurring at the puerperium, and that, as a puerperal patient may have a large number of different fevers,

the words are indefinite and mean nothing. It suggests that we use the terms "puerperal infection" or "puerperal sepsis," or whatever specific disorder the patient may be suffering from.

Teaching University for London.—It would be a great source of comfort to readers and subscribers to London medical journals if the question of a "Teaching University for London" could be definitely settled. For a decade now, a large amount of valuable space—editorial annotatory, and so forth—has been devoted to arguments upon this most recondite and interminable topic. We beg the citizens of London to cease verbigeneration and either to have a university or not, at once. We ask this for the sake of those who have loved to peruse the one-time valuable pages of the medical journals of that town.

The Medical Students and Doctors in Germany, though they have to serve a full year in the army, have heretofore been kept under arms for only six months. The authorities have lately decided to call in the doctors for a short period of service in the years following their dismissal from active service. The Berlin correspondent of *The British Medical Journal* says that this news has caused a great deal of excitement among the young doctors, who find it difficult enough to build up a practice without being called away for four or six weeks during the midst of their work.

The Cities of New York and Berlin issue cards to physicians for the purpose of enabling them to pass unhindered through a cordon of police or other obstruction to the general circulation. This example has been followed by the city of Paris, the chief of police having made arrangements for issuing similar cards of identification to the medical men of the capital.

Infective Books.—Drs. Ducazal and Catrin have concluded from experiments (*Paris Acad. de Méd.*, December 17, 1895), that while new books show no pathogenic microbes, library and hospital volumes may transmit Klebs' bacillus and the streptococcus. Koch's bacillus and the pneumococcus, however, cannot be transmitted in this manner.

Sufficient Subscriptions have been received to justify the continuance of the publication of *The Index Medicus*.

The Third International Congress of Psychology will be held at Munich from the 4th to the 7th of August, 1896.

The Western Reserve Medical School has effected a combination with the Lakeside Hospital, by which the latter institution will be under the control of the faculty of the school and will thereby be used for teaching purposes.

A New Surgical Polyclinic in connection with the Berlin University is to be opened shortly. Professor König is at its head, and Professor Hildebrandt its chief surgeon.

France has two Medical Men who are cabinet ministers—Dr. Viger, Minister of Agriculture, and Dr. Combes, Minister of Public Instruction.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 23, 1895.

EDWARD D. FISHER, M.D., PRESIDENT.

Prolapse of the Rectum with Special Reference to the Obscure Forms and their Reflex Phenomena.—DR. JAMES P. TUTTLE read the paper on the above subject. (See p. 38.)

DR. A. P. GERSTER, in discussing the paper, said he was very grateful to the writer for bringing forward a condition of the rectum not often spoken of or written about. He would rather favor the term intussusception for the condition described by Dr. Tuttle, and apply the term prolapsus to that condition in which the gut extended beyond the anus. As to the affection proper, he was astonished to hear Dr. Tuttle say it was so common, for though he was in reach of an immense amount of material at the Mount Sinai Hospital, he had not met the condition so often as to be impressed with its frequency. He believed the operation by which the gut was lifted and attached to the abdominal wall was often a successful cure, but there were cases in which it was not at all applicable, for in some instances there was a hypertrophy of the rectum so large and indurated as to resemble elephantiasis. In these cases the rectum had to be amputated.

DR. J. D. BRYANT said he would like to join Dr. Gerster in thanking the gentleman for the paper. The frequency of the condition was greater than he had supposed, but he presumed Dr. Tuttle had greater opportunity than he for seeing such cases. The patient whom he had operated upon, and to whose case Dr. Tuttle had referred, entered the hospital in 1891, without having obtained any benefit from six operations which had been performed for the relief of a prolapsus of the rectum. The operations which had been performed had been done in the manner which seemed to meet existing conditions. The patient came under his care in March, 1893, with complete prolapsus and the sphincter entirely paralyzed. In view of the fact that so many operations had been performed and failed, leaving incontinence, he decided to do colotomy, and later operate upon the prolapsus. He performed an ordinary colotomy, and in three weeks the patient got up, left the hospital, and did not return until the next fall. Before the colotomy the patient had suffered from colicky pains, diarrhoea, and tenesmus, which were quite constant. When he returned in the fall the prolapsus was within the sphincter, and did not come down except on straining, and his physical condition was much improved. About one-third of the fecal matter continued to pass through the bowel. In 1894 he presented the patient at a surgical meeting of the Academy, when, by straining, a prolapsus of about one-fourth of an inch could be exposed. The case was not cured. He had drawn the following conclusions when he presented a paper on the subject at the time: 1. That the proper performance of the physiological function of the rectum contributes greatly to the advancement of rectal disease and to the suffering of the patient. 2. That the complete vicarious discharge of the feces through an artificial anus located at the sigmoid flexure reduces the physiological demands upon each structure of the rectum to a minimum. 3. The lessening of the physiological requirements is commonly in direct proportion to the diminution of the faecal flow through the rectum. 4. The cessation or lessening of the faecal discharge through the rectum exercises a palliative or curative influence on the diseases of the rectum. 5.

In certain cases of obstinate rectal prolapse, the formation of a vicarious channel for the faecal discharge is justifiable, both as a palliative and as a curative measure. 6. The establishment of such a channel for the purpose of cleanliness and prevention of infection is justifiable in many operations for prolapsus of the rectum. 7. That the dangers of formation of artificial anus are much less than those invited by contact of faecal discharges with large operative surfaces of the rectum. 8. The case presented had been greatly benefited, and may finally be cured by the agency of an artificial anus. Dr. Bryant said he wished to add that the patient had not been cured but was greatly relieved, and while there was no protrusion, he was still conscious of a feeling of weight in that region.

DR. JOHN ERDMANN said the first patient he tried to relieve by attaching the meso-colon had a large ulcer, and had experienced much pain on defecation. He operated in January, 1894, and also formed an artificial anus. The prolapsus was much relieved, but the ulcer being tubercular, the patient died later. At autopsy he found the adhesions desired by the operation firmly formed. In the second case he attached the colon itself by the anterior longitudinal bands to the peritoneum. The patient had no prolapse until the last sixty days. In the third case he had operated upon he attached the meso-rectum to the side wall, and then the longitudinal fibres to the abdominal wall. He let the patients go around in about fourteen days.

DR. WILLIAM H. MCENROE said he wished to call attention to a remedy for the treatment of prolapsus of the rectum from a medical standpoint. He had found that hypodermatic injection of strychnine was very beneficial. After the gut has been replaced, inject the strychnine into the folds of the intestines, beginning with one-sixtieth of a grain, and gradually increasing to one-twentieth. He knew one case that had shown symptoms of strychnine poisoning, yet the prolapsus was greatly improved. It should be remembered that the strychnine should be given hypodermatically, and not by the mouth.

DR. SENECA D. POWELL said his views were so entirely different from those expressed by the speakers that he felt a little diffident. He did not believe any operation was necessary for prolapsus of the rectum. In 1878 his attention was called to a case, the study of which led him to conclude that not enough was known of the cause of prolapse, and by research he came to the conclusion that it was an anatomical fault. To appreciate the mode of treatment it was necessary to remember the physiological process and the anatomical relations in defecation. The natural and proper position in defecation was the squatting position, as evidenced by the difficulty experienced by trying to defecate in the erect position. The sphincter ani muscle held the balance of power between the muscles of expulsion—the diaphragm, abdominal muscles, and the levator ani—and the muscles which guarded the outlet of the pelvis—the levator ani, the internal and external sphincters, the transversus perinei, and the accelerator urinae. The external sphincter was attached to the coccyx, the tendinous centre of the perineum and the skin. The squatting position caused the rotation of the pelvis upon the heads of the femurs; this drew the skin tight, and the sphincter ani was pulled open laterally. It should be remembered that the levator ani often contained long fibres which passed in and between the sphincter ani and the rectum, and extended up the gut three or four inches, and was inserted into it. If for any reason the tendinous centre of the perineum was affected, the support of these muscles attached there was interfered with, and the result was necessarily a prolapsus in every case where there were long fibres of the levator ani. The mode of treatment was therefore to overcome the cause

by providing a support for this tendinous centre of the perineum. For this purpose the patient was laid on his belly, and by means of a strip of adhesive plaster passed along the line of the gluteal fold, the buttocks were pushed upward and inward, forming a support for the affected parts and a rest for the muscles of the perineum until they regained their normal condition. Dr. Powell had presented a paper on this subject before the Northwestern Medical and Surgical Society in 1878, and from that time on had used the method successfully, not having had a single failure. The patient should wear the strip all the time, especially during the act of defecating, after which the parts should be cleansed and a new strip applied. Dr. Powell said Dr. Bryant's case illustrated this principle, and that if he had taken all work off the part by means of the artificial anus, the patient would doubtless have recovered entirely.

In closing the discussion, DR. TUTTLE said he had mentioned in his paper that there were many cases which were not suited for this mode of treatment. He was not surprised that the gentlemen did not find so many cases of prolapsus of the third degree, for the patients did not complain of this condition. He believed if Dr. Bryant had drawn up the prolapse he would have cured his patient. The cause of one-half of the failures was neglect in carrying out treatment during inflammatory conditions.

The Preventive Treatment of Sea Sickness.—

DR. A. D. ROCKWELL read a paper on this subject. The literature, he said, was very extensive. The disease had become something of a byword. The general idea prevailed that it was good for the system, and there was also a general belief that it was not possible to do anything that would prevent or help the condition materially. Little systematic research had been made by ship surgeons, for they did not often meet the patients until nausea had set in, and then the disease was permitted to take its course. No physician believed seasickness came from the stomach alone, but more probably from mild concussions of the brain. The use of the bromides before sailing was of great benefit. He would not say all cases of seasickness would be prevented by this means, but it would prove serviceable in most cases. To get the desired effect, bromization must be secured before sailing. He had always suffered very much from seasickness, and so feared to sail for Europe, but by taking a hundred grains a day for three days preceding sailing, and continuing the bromide three or four days after sailing, he had escaped being seasick. His experience was that bromization was not disagreeable, aside from a little drowsiness, from which the mind readily aroused, while the sleep taken during the period was very sound and refreshing. Though the English Channel was very rough when he crossed it, he did not get seasick, for he prepared himself by taking bromide for two days preceding the time of sailing. Dr. Rockwell cited a number of persons who had been accustomed to suffer severely when crossing the ocean, but who had entirely escaped by means of the bromide treatment. He emphasized the fact that it was not enough to take a few grains of bromide, but it was bromization that was necessary.

DR. MAX EINHORN said he had had some experience with bromide in seasickness. Before sailing to America the first time, he took bromide and did not get seasick, but feeling uncomfortable from the bromization he quit it and got very sick. There were some persons who did not bear bromization at all well.

DR. J. A. IRWIN said we ought to have some idea of the pathology of seasickness to appreciate the condition. The primary condition was a disturbance in the labyrinth of the ear. Any treatment that tended to anaesthesia would help that condition. Also any

treatment which tended to make the stomach less susceptible to reflex irritation was useful. It must be remembered that seasickness was a disease that cured itself, and that the individual could become habituated to the motions which produced the sickness. All persons did not respond to the same treatment, and the seasickness did not affect every one in the same way. In some it affected the head most, in others the stomach, and the treatment should be directed to the radical symptom. He objected to bromization on the ground that it was as bad as the disease it was designed to prevent.

Drs. William H. Haskin and J. L. Barton were elected delegates to the State Medical Society.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, December 3, 1895.

EDWARD D. FISHER, M.D., PRESIDENT.

Graves' Disease—Œdema of the Eyelids.—DR. J. ARTHUR BOOTH presented a case of Graves' disease with the presence of a rather rare symptom—œdema of the eyelids. On inspection the diagnosis of Graves' disease had been made, but the examination had revealed no exophthalmos. There was, however, slight enlargement of the thyroid and a rapid pulse. The patient, a girl of seventeen years, was very much frightened when quite young. She had some convulsions following this incident. About the time of her first menstruation œdema of the eyelids first appeared. She now complained of palpitation of the heart, profuse sweating, headache, and general weakness. This œdema, the speaker said, was not a true œdema, as it did not "pit" on pressure. The movements of the lids were harmonious. On palpation, swelling and diffused hardness of the thyroid could be made out. When seen about one month later, *i.e.*, December 2d, there was apparently a slight prominence of one eyeball. Four examinations of the urine had been made, but nothing abnormal discovered.

Cerebro-Spinal Syphilis.—DR. CHRISTIAN HERTER presented a young man, twenty-eight years of age, who gave a history of having had a chancre two years ago, and about one year thereafter developing various cerebral symptoms. The vision was first observed to become diminished in the right eye; then there was ptosis on that side, paralysis of the third nerve, paralysis of the facial nerve and of both trigeminal nerves. After this he developed weakness in certain muscles of the right arm. There was a history of rheumatism in the parents, and of alcoholism in the patient. About one year ago there was a purulent discharge from the left ear, which lasted for several months. One year ago the right eye was struck by a piece of hoop from a barrel. Shortly afterward he began to complain of double vision, and saliva drivelled from the right angle of the mouth. There had been at no time pain in the hand or forearm. Under the administration of iodide the patient had regained some control of the movement of the eye muscles and right eyelid. The physical examination on November 26, 1895, showed the man to be small and fairly nourished, with lateral curvature of the spine and considerable deformity of the thorax. There was slight ptosis on the right side. The right internal rectus was extremely weak, and there was paresis of the superior and inferior recti. There was sufficient power in the internal rectus to maintain binocular vision but not sufficient to preserve convergence. The reaction to accommodation was greatly impaired. R. V. was $\frac{2}{30}$ and L. V. $\frac{2}{40}$. Both optic discs were found to be distinctly paler than normal and the vessels slightly narrowed. Near the right disc were two patches of slight choroidal atrophy. All

the movements of the face were well performed, and there was no drivelling of saliva. Reaction of the facial muscles to faradism was well preserved. The temperature sense and tactile sense presented fairly well-defined areas. Sensation was preserved over the eyelids and was only moderately impaired over the nose. Near the lips sensations of pain and touch were slightly impaired. The uvula deviated to the left. The sense of taste did not seem to be distinctly impaired. There was some loss of power in both arms, but this was more marked on the right side. The flexors of the right wrist were weak, and those of the fingers were wholly paralyzed. The power of the pronators and supinators was normal. All the paretic and paralyzed muscles were wasted. All the paralyzed muscles showed the reaction of degeneration to a greater or less degree. The ulnar area of the right hand and lower two-thirds of the forearm showed loss of sensibility to pain, temperature, and touch. In the left hand and forearm there was a moderate loss of power in the flexors of the fingers. There was no wasting of the left forearm or any change in sensibility or electrical reactions. In both arms there was slight and rather coarse tremor when the arms were extended. There was no loss of power in the legs, and sensibility was not impaired. Both knee-jerks were absent, but the plantar and cremasteric reflexes were present. There was considerable oscillation on standing with the feet together and the eyes closed. The patient urinated without straining. There was frequent pain in the right hypogastric region, but no "girdle" pain. There had evidently been marked improvement during the past month under the use of iodide. The conditions present in this patient were undoubtedly due to the lesions of cerebro-spinal syphilis. The fifth nerves had been more damaged than the others.

The speaker said that the two points upon which he desired further information were: (1) The exact location of the lesions at the base; and (2) as to whether or not the patient had locomotor ataxia.

Discussion.—DR. W. M. LESZYNSKY said that he recalled having seen a man, about fifty-eight years of age, with very marked exophthalmos and goitre, associated with marked œdema of the eyelids. This œdema, however, had been absent in one eyelid for a time, and it had gradually disappeared.

DR. B. SACHS said that within the last few years he had seen upward of thirty cases of Basedow's disease, and yet he had never observed such œdema in any of these cases.

DR. BOOTH, in closing the discussion, said that he had been unable to find any mention of more than one case of the kind in English literature. It was interesting that no exophthalmos had been noticed until a few weeks ago. It had been suggested that the œdema was due to paralysis of the orbicularis.

DR. SACHS said that he agreed to the diagnosis of cerebro-spinal syphilis in Dr. Herter's case, but would prefer to have it called multiple cerebro-spinal syphilis. The involvement of a large number of cranial nerves and imperfect involvement of some of these nerves were especially characteristic features. He had made the diagnosis of cerebro-spinal syphilis several years ago in a case in which there had been complete trophic paralysis of the upper and lower extremities, with ptosis. One critic had looked upon this case as one of neuritis rather than of central disturbance. This view he did not accept, for we had only to suppose that the specific meningitis had extended along the ventral surface of the cord instead of laterally to explain the symptoms. The fact that there had been improvement in some of the symptoms under the use of iodide was, of course, very significant. In his opinion, there was no one symptom of

greater value than the complete immobility of the pupil to accommodation and light, or the equal impairment of both of those functions. This was very different from the Argyll-Robertson pupil. If in addition to this there was a multiplicity of lesions, the probability of syphilis was very strong. He would not think of making the diagnosis of tabes in this case, because there was absence of the Argyll-Robertson pupil, little or no pain, and no involvement of the bladder.

DR. HIRSCH said that he did not think we could exclude general paresis of syphilitic character. The expression of the face, the tremor and slight deviation of the tongue, all pointed toward this condition, and the diagnosis could not be made without further knowledge of the psychical symptoms.

DR. HERTER said that from his short acquaintance with the patient he felt that the psychical symptoms usually observed in general paresis were not present. His mental condition and memory were quite good, and his slight imperfection in articulating seemed to be due to an imperfect co-ordination of the lower speech mechanism. The expression of the face appeared to be due to the ptosis.

THE PRESIDENT said that he would certainly agree with the diagnosis of cerebro-spinal syphilis, and also regarding the points of localization at the base of the brain.

DR. IRA VAN GIESON said that he wished to indorse the term "multiple" cerebro-spinal syphilis from a pathological standpoint. Syphilis of the nervous system should be considered in three forms: (1) The multiple variety appearing in the form of plaques; (2) the form in which there were discrete gummata; and (3) the form in which there were less tangible lesions of the blood-vessels and interference with the nutrition of the blood-vessels.

DR. SACHS said that through recent researches the endarteritis of the spinal cord had been very definitely established. The specific endarteritis of the cerebral vessels had been recognized for a long time, but more recently it had been very definitely established in some of the cases of spinal syphilis that there was a specific endarteritis of the vessels of the spinal cord with areas of softening in the spinal cord. The speaker said that a few years ago he had been inclined to consider these cases as examples of meningeal infiltration extending gradually inward through the entire cross section of the cord.

THE PRESIDENT said that most of the symptoms of general paresis were of later origin than those present in the case under discussion. This patient had already shown improvement, therefore the symptoms must be due to specific infiltration at the base of the brain, and also possibly to softening in the cord from an endarteritis—a condition shown to exist many years ago. This was essentially different from the chronic condition present in general paresis.

Report upon a Case of Progressive Muscular Dystrophy, with Especial Reference to Improvement by Treatment.—DR. A. WIENER presented a case of this kind with the idea of showing that such a case could be improved by treatment. From a review of the literature he said that it was apparent that the tendency now was to bring the disease formerly divided into spinal and myopathic forms under one head. The patient to be presented this evening, he said, had been exhibited two years ago before this society. At that time he had been twenty years of age, and had been perfectly healthy up to May, 1892, and had not experienced the slightest difficulty in performing any muscular movements. The first indication of difficulty was in May, 1892, when he began to suffer from vague pains in the region of the spleen and liver on considerable muscular exer-

tion. Shortly after this, difficulty in going up-stairs and in walking was observed, and soon atrophy of the lower extremities and back was observed. Finally the muscles of the neck and face became involved. The patient denied alcoholism or syphilis, and stated that his health had been excellent. He had noticed while engaged in athletic sports that the muscles of the upper extremities quickly became fatigued. In 1893 there was no distinct abnormality about the formation of the skull. His general appearance was that of a person very much emaciated, and there was great difficulty in walking and lifting the limbs. On attempting to stand upright, he exhibited a marked lordosis. When lying down, it was impossible for him to turn over. The muscles were soft and covered with redundant skin. No vasomotor or trophic disturbances were discovered. The deep reflexes were absent on both sides. The spinal column was in no way tender on percussion. Examination of the muscles showed a marked paresis. The muscles of the forearm and hand appeared normal. Mechanical excitability was very much diminished. Electrical examination gave quantitative changes, but no reaction of degeneration. The abdominal muscles were only slightly affected. The orbicularis oris and palpebrarum were the ones chiefly affected about the face. The deltoid muscle showed simple atrophy of the muscular fibres, with cell infiltration in the muscle and between the fibres. No hypertrophy of the fibres could be found, and there was no evidence of fatty deposit. The small blood-vessels were filled with blood, and the walls with round cells. The lack of all sensory disturbances left no doubt that this was a case of the myopathic type. No improvement was noticed under the usual tonics and electrical treatment, so it was decided to try the effect of physical culture carried on daily to the point of exhaustion. From half an hour to one hour were devoted to exercises with dumb-bells, Indian clubs, and the use of a health-lift machine. There was evidence of very marked improvement in every way. Quite lately he had been able to ride forty miles in one day on a bicycle. Some of the muscles still showed atrophy. The improvement was especially marked in the muscular movements and in the partial return of the contour of the parts. The speaker said he did not think such treatment would be efficacious in cases developing in infancy, but where there had been a good development prior to the appearance of the disease, this plan of treatment offered a good prospect of success.

Discussion.—DR. G. M. HAMMOND said that the heart symptoms in this man were very much like those seen in individuals who had received too much physical exercise at a time when the heart was feeble. This man's heart was dilated and hypertrophied, and it was possible that this was due to a loss of muscular tissue as a part of his disease. He asked if Dr. Wiener thought the arrest of the atrophy might not have been spontaneous and independent of the physical exercise. He had himself seen one or two less extensive cases of dystrophy in which the atrophy was recovered from without any treatment. In one of these cases the atrophy was limited to the muscles of the thumb in both hands.

DR. C. L. DANA said that he thought there was a class of cases of progressive muscular dystrophy brought on by excessive muscular work when the person was immature. This form of dystrophy seemed to him to have a different course from the ordinary types of dystrophies. He had seen cases in which he believed the lesion was in the muscles, and in which the course and clinical symptoms were those of dystrophies occurring in acrobats and gymnasts. In these cases the symptoms usually progressed steadily up to a certain point, and then there was an arrest of the

process, and sometimes a very decided improvement. This clinical distinction should be borne in mind in estimating the value of the treatment pursued in this case. He doubted very much if such treatment would have much effect on the more usual form of atrophies. In the cases to which he had referred the upper arm, shoulder, and back were usually affected.

DR. SACHS said that the case seemed to him of great importance. He was perfectly familiar with the class of cases referred to by the last speaker—the localized atrophies and those due to excessive muscular exercise. The case under discussion, however, did not belong to this category. When first presented to the Society two years ago, the involvement of the facial muscles was a prominent feature and the improvement observed had been in the muscles other than the facial ones. There was, of course, room for doubt as to the value of this particular treatment, yet it should be remembered that no improvement had been observed under other methods, and yet it was prompt and decided under physical exercise systematically carried out. The original diagnosis of progressive muscular dystrophy was without doubt correct, and the result of treatment was certainly unique.

DR. JOSEPH COLLINS said that where the proton was diseased it should be evident that no amount of mechanical treatment would be of service, but if the form of progressive muscular atrophy were acquired, then treatment including exercise should be of some advantage. He thought, therefore, the case was very instructive. It was begging the question to infer that the improvement was independent of the treatment. He believed this to be a case of progressive muscular dystrophy of the acquired type, no evidence having been brought forward to show that it was either familiar or hereditary, and that the improvement was due to the treatment.

DR. HAMMOND said that the man had been an athlete and a runner, and yet had developed the muscular dystrophy; hence he could not understand why if the muscular atrophy had developed during exercise, it should be arrested and improved by a resumption of systematic exercises.

DR. HERTER said that the case was evidently one of the family form of progressive muscular dystrophy, and he felt that the systematic exercise must have had a beneficial effect in bringing about this change. One should not, however, draw too positive conclusions from one or two cases. The case was a most interesting example of what could be done by modifying favorably the nutrition of a part.

THE PRESIDENT said that as far as the distribution of the dystrophy was concerned we certainly found cases in which it was exactly similar, and yet we could not trace the exact etiological factor. Where the hereditary element was not present, it was possible that there was a better chance for improvement under treatment. He thought that we were warranted in trying systematic physical exercise, at least in cases in which the hereditary factor was not especially prominent.

Tumor of the Medulla.—DR. JOSEPH COLLINS presented a pathological specimen with the following history: S. J. J.—, twenty-eight years of age, denied syphilis and had been extremely temperate. The first symptom, numbness in the fingers of the left hand, was observed eight months ago. This gradually spread up the arm, and later on a similar feeling was noticed in the left lower extremity. About five months ago he became so unsteady that he had to give up his work as a bricklayer but continued working in a factory till two months ago. About three weeks ago he observed a "stiff feeling" in the left side of the head, and the left upper and lower extremities felt unwieldy. On November 22d, when first seen by the

speaker at the request of Dr. Kelly, the head was fixed and slightly drawn to the left. There was no real stiffness of the head, and no abnormality or tenderness. There was no ocular paralysis; the pupils responded to light and accommodation. The fundus was found quite normal. Vision and color perception were normal. The sense of smell and taste were normal. There was no unsteadiness of articulation. The knee-jerks were both exaggerated, particularly on the left side, and there was likewise left ankle clonus. The triceps reflex was exaggerated on the left side. The left hand was decidedly ataxic. The patient could walk, and could move the upper extremity in every direction. There was a remarkable diminution of the pain sense all over the body, including the mucous membranes. Tactile sensation appeared to be unimpaired. Temperature sense was exquisitely preserved. The patient talked rationally and the psychological sphere was intact. Examination of the urine showed albumin but no sugar. The pulse was rapid, the respirations accelerated, and the temperature 102° F. The opinion was expressed that the intra-cranial lesion could not be satisfactorily localized, but that there was probably a new formation within the brain subcortically, involving the pyramidal projection on the right side. Three days later the patient was seen again, and was found much worse. He was quite somnolent and the reflexes had become quite sluggish. There was already marked pulmonary oedema. An exploratory opening was made by Dr. J. E. Kelly, the surgeon in attendance, just behind the fissure of Rolando. A hollow needle introduced into the brain in various directions found no unusual collection of fluid. On the second day after the operation his temperature rose to 105° F., although there was no evidence of sepsis in the wound. He died December 1st. It was found on autopsy that a large part of the medulla had been destroyed by the tumor, leaving only a mere shell. The remarkable feature of the case was that the man appeared to be well in every respect up to a short time before his death, and yet nearly all of his medulla was gone.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 16, 1895.

DR. S. B. W. McLEOD, PRESIDENT, IN THE CHAIR.

Sprained Ankles.—DR. E. VON DÖNHOFF opened the discussion upon this subject. He said he had intended to speak not only of sprained ankles but sprains in general. Sprained ankle was the most common form in which that kind of injury known as sprains was found, and it was not a matter of such small importance as to render it contemptible in a diagnostic sense to the physician. A correct diagnosis was pre-eminently important, as upon the correct knowledge of the injury the treatment depended. Every joint was an exceptionally complex machine in reference to its structure, especially as to its synovial membrane, which was so sensitive that an injury often gave rise to conditions which impaired or rendered useless the joint. It was therefore necessary to determine as nearly as possible the extent of the injury—whether there was an injury of the bone, the soft parts, or the cartilage, for upon these primary conditions rested the treatment. Having determined the extent of the injury, the next thing was to adopt the line of treatment which was the least cumbersome to the patient and assured the readiest cure. Treatment by massage had been recommended by many, but there were cases in which that would result in serious and lasting injury. Neglect of the first principle, absolute

rest, was often a source of permanent impairment of the joint.

In stepping from her carriage a lady had sustained an injury to the ankle which a doctor said was a sprain and suggested bathing. Another doctor diagnosed the case as osteomyelitis and proposed to open the part and let out the pus. The result was, the limb was amputated and the bones were in a softened condition. Dr. von Dönhoff said he was satisfied no serious result would have taken place if the limb had been correctly treated at first. The result of an injury to a joint depended much on the diathesis and age of the patient. A young patient under the age of puberty with tubercular diathesis was very prone to chronic disease of the ankle-joint, or any other joint which had been injured. Slight injuries might appear as nothing to those who had not seen the evil results which sometimes followed such injuries. It was often true that when treated as well as they might be they resulted badly. For example, a number of years ago he had had a child brought to him who had received a sprain a year before and had been well treated, nevertheless he had diagnosed it as a case of dry caries and operation proved the diagnosis correct. It might be truly said that it was not always easy to make a diagnosis, and it was not proper to say to the patient it was only a sprain and of little importance. A favorable prognosis should not be made unless the patient was willing to remain at rest until all pain had ceased. Dr. von Dönhoff said that a sprain of the shoulder often resulted in a helpless shoulder. He had such a case now in a man who fell from a wagon and had not fractured a bone or injured the joint but had injured the deltoid muscle.

Dr. J. F. ERDMANN said he had hoped Dr. von Dönhoff would take up the treatment of sprains. As for the diagnosis, he thought that by taking hold of the joint firmly and making pressure so as to put the ligaments on the stretch the point of pain would aid in locating the point of injury and making the diagnosis. In treating sprains it had been his custom to put on evaporating lotions and then apply splints. More recently he had been using the methods of fixing the joint by means of adhesive plaster, beginning below the injury and extending above the ankle, and then allowing the patient to go about. Dr. Stewart and he had been treating in this way the wrist-joint. In cases of synovitis, if the fluid persisted, he had resorted to the aspirating-needle and removed part or all of the fluid. Every one knew that the family history must be taken into consideration in giving a prognosis, and also that a sprain was not an injury to be lightly considered.

Dr. JUDSON said that sprains as a general thing occurred in the lower extremity, due to the difference in mechanical relation, but were it possible to conceive of men walking on their hands this might be changed. He thought that this gave the hint to the treatment: remove the affected part from the influences of walking and standing. A very simple way to take the weight of the body from the affected limb was to put the patient on crutches and elevate the sole of the shoe on the well foot. The pathology was very interesting, but from the nature of the condition was very obscure. Some cases of joint disease seemed to have had their origin in a sprain which was long continued and not very susceptible to treatment.

Dr. LIVINGSTON said he thought patients with sprains did better with a limited amount of motion. It had been his practice, if the patient was seen shortly after the injury, to put the part up in adhesive plaster as Dr. Erdmann described, but if he saw the patient a day after the injury he used the Martin bandage for a few hours to reduce the swelling before putting on the adhesive plaster. He agreed that but little was

known of the pathology of sprains, and therefore much of the treatment had been more or less in the dark, but clinical experience proved that to put the ligaments to rest by means of the adhesive-plaster bandages and not interfering with the joint was beneficial.

Dr. HENRY said he liked the James F. Little form of treatment. By the use of plaster-of-Paris splints, moulded to the leg and leaving a space between them, then strapping with bandages, a dressing was formed which gave good results and furnished the opportunity for applying new bandages.

Dr. GROW said he thought hot water was excellent in treating sprains. By putting the limb in hot water all pain was relieved. This use of hot water for the relief of pain was not new, and Napoleon had used it when on St. Helena to relieve the pains he suffered from cancer. Hot water, like sleep, brought back to the circulation the fluids of the body, and in sprains was useful to give relief preceding bandaging.

Dr. GALLANT said the speakers did well to lay stress on the serious results often arising from sprains. He also had a case of a man who had fallen and injured the shoulder similar to the case mentioned by Dr. von Dönhoff. He sent the patient to Dr. Peterson for test with electricity and it was found that the injury was in the muscle itself. Dr. Gallant used massage and found that patients did very well under that treatment. It was claimed that by massage the time for recovery was reduced one-fifth of that usually required. In using massage the injury itself should not be massaged at first, but the manipulations should begin above the injury and gradually work toward it, the strokes being made all the time up and from the injury. In this manner the swelling was removed and if the procedure were continued for a time the patient experienced great relief, for the swelling was always the cause of the pain. The usefulness of massage in diagnosis should especially be remembered. It was a desirable method of treatment to prevent ankylosis, for fibrous deposit was prevented and nothing was left to cause ankylosis.

Dr. MANLEY said that sprains were due to a diversity of causes and in quite a number trauma was only an element. As there was often a weakening of certain sets of fibres favoring dislocations, so there were conditions favoring sprains. There was no doubt that rheumatism was a predisposing factor in many cases. In his opinion no particular line of treatment would fulfil the indications in all cases. Fixation would cure many cases in a short time, but some proved quite obstinate and did not recover under this alone. The pathology of some cases was especially obscure, as in a case in which there was no swelling, no hemorrhage, but persistent pain and soreness. This class belonged to what was known as arthritic neurosis. Dr. Manley said in going over the literature of the subject of sprains he had come to the conclusion that there were many cases in which there was a psychical element and some of them should be treated by taking the limb and breaking up the adhesions without anesthesia. The pain and slight mental shock with the breaking up of the adhesions produced the desired effect.

Dr. T. D. MERRIGAN said he thought the loss of use of the shoulder-joint in the case mentioned by the first speaker was due to an injury of the brachial plexus which passed down just in that region. Such an injury was not uncommon, especially where the individual fell but a short distance and the plexus was unprotected by the contraction of the muscles. For that form of injury he thought electricity was the treatment. When there were adhesions the application of the negative pole of the galvanic current would tend to the resorption of the deposits and the breaking up of the adhesions. Dr. Merrigan said he agreed that massage was good, but a great many patients were not able to hire the services of the experienced

masseur to visit them twice a day. The adhesive-plaster bandage lent a support and was useful. If a correct diagnosis could be made, pressure by means of cotton batting and bandages could be applied to the part in such a way as to give relief and lend support.

In closing the discussion DR. VON DÖNHOF said he thought those injuries which could be treated by massage must be slight, for the more serious injuries required some time for recovery. If there was a rupture of the ligaments it seemed unreasonable to think the structures would heal while the patient was going about on the limb. As soon as a limb was injured, Nature at once, by a stiffening of the muscles from nervous reflex, attempted to put the part to rest. Acting upon this suggestion it seemed to him the most reasonable method was to seek mechanical rest for the injured part. He did not mean put the part in a plaster cast which would result in more or less ankylosis, but in all of the severer sprains with injury in and about the joint secure for the part absolute rest, and, as was largely the present custom of treating fractures, begin passive motion about the third day. He did not believe that pain could be entirely relieved by massage, but the thankful patient often drew on his imagination out of gratitude to the surgeon. He thought electricity was useful in many cases, especially chronic ones, but it was often useless; for in his opinion there was a certain amount of paralysis, or, at least, paresis associated with these injuries.

Clinical Report of a Case of Excision of the Head of the Humerus and Half of the Glenoid Fossa of the Scapula.—DR. JOHN F. ERDMANN presented the patient, aged forty-four, a builder, family and early history negative. On December 15, 1894, he fell, striking on the anterior aspect of his left shoulder. He remained at home three days suffering intense pain, was removed to a hospital where dislocation of the shoulder was diagnosed, was anesthetized, and reduction said to have been made. On December 28, 1894, he was admitted to another hospital with above history and the additional symptoms of inability to use his left arm and great pain in the elbow, wrist, and hand of the same side. He was twice anesthetized and each time so-called reduction was accomplished, but it did not remain reduced. On August 29, 1895, ten months after the original injury, and after three attempts at reduction had been made with the patient under ether, Dr. Erdmann said he found the following: Marked emaciation of the upper half of the trunk, flattening of the left shoulder, prominence within one-half inch of the under surface of the clavicle, a large and round mass beneath the coracoid, and evidence of some bony substance filling the glenoid cavity. A diagnosis of fracture of the head of the humerus with dislocation and possible fracture of the coracoid process was made, and the patient accepted operative interference. While manipulating the arm after anesthesia a distinct snap was heard, the arm became freely mobile but with crepitation. An incision was made and upon exposing the wound a mass of callus was found at the site of the greater tuberosity and extending up into the glenoid fossa, while internally and beneath the coracoid process the head of the bone was found; these two portions were separated by a fissure from which there was free oozing. This fissure accounted for the snapping heard during the manipulation, and was a fracture of the head from the side of the shaft where it had become attached by callus. Reduction of the displaced head was impossible. The incision was enlarged, the head of the humerus chiselled out; the anterior half of the glenoid cavity of the scapula had been broken and was solidly united with the head of the humerus, the long head of the biceps was embedded in a mass of callus on the humeral head and by pressure had been atrophied to

one-half its size at other points. The callus upon the greater tuberosity was removed with a saw, and the wound cleaned out and sewed up with catgut. Twenty days later the dressings were all removed and passive motion begun. On December 14th, about three months after the operation, the patient could abduct the arm to forty-five degrees, could place the hand on his right shoulder, forward and backward motion was good, rotation slight, and the functions of the elbow, wrist, and fingers were excellent.

Carcinoma of the Leg Following a Compound Fracture.—In presenting the specimen Dr. Erdmann gave the following history: Male, aged sixty-seven, laborer. About forty years previous he had sustained a compound fracture of the tibia, the bone had united, but the wound never thoroughly healed, but yielded a constant discharge. In August, 1894, the patient was anæmic, emaciated, poorly nourished, feeble, and with a temperature $99\frac{1}{2}^{\circ}$ to $100\frac{1}{2}^{\circ}$ F. There was an old unhealthy ulcer with hardened and indurated edges, connected with the tibia and covered by a sero-purulent discharge with marked odor. As the high temperature was of recent date and exhaustion was becoming more marked, amputation was proposed and accepted. Disarticulation was done at the knee joint; patient did nicely for three days, then the temperature ran to $102\frac{1}{2}^{\circ}$ F., he became melancholy, refused food after the sixth day, and died on the thirteenth day after the operation. Diagnosis of carcinoma was made by the pathologist.

Reviews and Notices.

ELEMENTARY TECHNIQUE IN HISTOLOGY AND BACTERIOLOGY. By EARNEST B. HOAG, A.B., B.S., Instructor in Zoology and Physiology, Throop Polytechnic Institute, Pasadena, Cal., and K. KAHN, Ph.D. (Mich.), Assistant Demonstrator in Bacteriology, Northwestern University Medical School, Chicago. Chicago: E. H. Colegrove & Co. 1895.

A SHORT manual, giving in a concise manner the technique of histological and bacteriological procedures. Designed for students or beginners in these branches it would serve them for ready reference, as it gives in tabulated form all the various steps requisite for preparing and staining the different tissues and bacteria.

THE PRINCIPLES AND PRACTICE OF MEDICINE, designed for the use of Practitioners and Students of Medicine. By WILLIAM OSLER, M.D., Fellow of Royal College of Physicians, London; Professor of Medicine, Johns Hopkins University. Second Edition. New York: D. Appleton & Co. 1895. 8vo, pp. 1,143.

IN studying the second edition of this admirable work we are struck with the careful and judicious efforts of the author in his attempts to bring all his subjects up to the level of the advanced thought of the day. Although scarcely less could be expected from one who has for so many years as a teacher kept in the lead, it is nevertheless gratifying to note the fact and to congratulate author and reader accordingly. We need refer only in a general way to the practical character of the treatise, its concise style, its reasonable and authoritative statements, and to the natural and systematic arrangement of subjects, as such features can be duly appreciated only after careful examination. A large amount of new matter has been added to the present edition, incorporating all the new and well substantiated facts that recent progress in medicine, pathology, and bacteriology have brought to light. In such respects the work can serve the double purpose of study and reference regarding essential progress in medicine. Among articles that have been either recast, rearranged, or rewritten we may mention typhoid and malarial fevers, diphtheria, cholera, syphilis, tuberculosis, gout, diabetes, chronic tonsillitis, anæmia, leukæmia, muscular atrophies, and psorospermiasis. The subjects that have been added are those on bubonic plague, infantile scurvy, eczema of tongue, affections of the mesentery, anuria, and Cheyne-Stokes breathing. To such as know the superior excellence of the previous edition it is

unnecessary to say that the present is a model of its kind, while to such as may study this one it can safely be said that it will give most ample satisfaction. Its peculiarity is that it represents the best work of a master in his art.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Tenth Session. Vol. X. Philadelphia, 1895. 8vo, pp. 406.

AMONG the notable papers in this always welcome volume are those on immunity against vaccination by Dr. Sternberg, Madura foot disease by Dr. Adami; hyperthermy in man by Dr. Jacobi, intra-thoracic tumor by Dr. Pepper, and by Dr. Welsh on the treatment of diphtheria by antitoxin.

TRANSACTIONS OF THE MICHIGAN STATE MEDICAL SOCIETY FOR 1895. Vol. XIX. Grand Rapids, 1895.

THIS is a goodly-sized volume, well filled with practical papers, some of them treating of rare affections which are well illustrated in full-page lithographs. Among the latter may be mentioned an interesting case of aural sarcoma and one of diffused pigmented sarcoma.

PRACTICAL URANALYSIS AND URINARY DIAGNOSIS. A Manual for the Use of Physicians, Surgeons, and Students. By CHARLES W. PURDY, M.D., Queen's University; Fellow of the Royal College of Physicians and Surgeons, Kingston; Professor of Urology and Urinary Diagnosis at the Chicago Post-Graduate Medical School. Second, Revised Edition. 8vo, pp. 360. Philadelphia: The F. A. Davis Co. 1895.

THIS compactly written and well-illustrated manual has advanced to a second edition, which, with numerous revisions and additions, both in text and illustrations, presents itself as a most useful and trustworthy aid in uranalysis and urinary diagnosis.

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF SKIN DISEASES. By ARTHUR VAN HARLINGEN, Ph.B. (Yale), M.D., Emeritus Professor Dermatology in Philadelphia Polyclinic. Third Edition. Philadelphia: P. Blakiston, Son & Co. 12mo, pp. 577.

THIS edition has been considerably enlarged, and in many respects is markedly improved as compared with the previous ones. The additions are mainly in the direction of introducing short accounts of the rarer diseases and the appending of notes for references. The illustrations are typical and sufficiently numerous.

OUTLINES OF PRACTICAL PHYSIOLOGY: Being a Manual for the Physiological Laboratory. By WILLIAM STIRLING, M.D., Sc.D., Brackenbury Professor of Physiology and Histology in Owen's College and Professor in Victoria University, Manchester, England. Third Edition. Philadelphia: P. Blakiston, Son & Co. 1895. 12mo, pp. 402.

THIS is a very practical work for the use of the student engaged in laboratory work, especially in those departments of chemical and experimental physiology which refer to practical medicine. Although the essential features of the previous editions remain unchanged, there has been considerable rearrangement of matter and many additions, including a short appendix on recording apparatus.

TRANSACTIONS OF THE AMERICAN GYNECOLOGICAL SOCIETY. Vol. XX. For the year 1895. Philadelphia: W. J. Doran. 8vo, pp. 633.

THIS is an unusually good volume, containing numerous special papers of marked value along the new lines of gynecological work, and has the additional value of a general index to the preceding volumes.

THE MEDICAL RECORD VISITING LIST AND PHYSICIAN'S DIARY FOR 1896. New Revised Edition. William Wood & Company, New York.

THIS visiting list is one of the oldest in the market, and its continued popularity shows conclusively the esteem which its convenient arrangement, good materials, and attractive make-up merit. The thirty closely-printed pages which precede the visiting list proper have just been revised and brought completely up to date, and the tables of equivalents, posological table, tables of formulae for various purposes, of poisons and their antidotes, together with many other memoranda on subjects of daily interest to physicians, are most complete. It is arranged for thirty or sixty pa-

tients per week, either dated for 1896 or without dates, so that it may be used indefinitely. The arrangement for recording visits and memoranda and cash account is excellent. The binding of the Medical Record Visiting List is of the best morocco leather, soft and flexible and extremely durable.

THE MEDICAL NEWS VISITING LIST. 1896. Philadelphia: Lea Brothers & Co. 1895.

ARRANGED for thirty patients weekly, and containing all kinds of information from "the signs of dentition" to "ligation of the dorsalis pedis." This year's record of practice is up to its usual style, is enclosed in an attractive cover, and has a thumb index for the various departments.

SURGERY: A Practical Treatise, with Special Reference to Treatment. By C. W. MANSELL MOULLIN, M.A., M.D. (Oxon.), Fellow Royal College of Surgeons, Surgeon and Lecturer on Physiology to the London Hospital. Assisted by various writers on special subjects. Third American Edition. Revised and Edited by JOHN B. HAMILTON, M.D., LL.D., Professor Prin. and Clin. Surg., Rush Medical College. Philadelphia: P. Blakiston, Son & Co. 1895. 8vo, pp. 1,250.

THE third American edition of this work appears as another candidate for favor among the numerous and more recent works on surgery. The topics are well and judiciously condensed, in order to compass the wide range of topics comprised under the head of general surgery. The illustrations are well selected and sufficiently numerous for their purposes, many of them being original. The demonstrations of operative technique are everything to be desired, and although a few are not up to the higher requirements of artistic conformity, they may be condoned in view of a laudable endeavor of exemplifying a laudable motive. The editor has done his part very judiciously, and proves his good taste by making very few annotations, which, for the most part, are very excusable, in his efforts to incorporate his own experience and that of other American surgeons in several special lines of work.

MENTALLY-DEFICIENT CHILDREN, THEIR TREATMENT AND TRAINING. By G. E. SHUTTLEWORTH, B.A., M.D., etc. London: H. K. Lewis, 136 Gower Street, W. C. 1895.

COMMENCING with an historical retrospect, this manual is divided into nine chapters. In the second chapter we learn of Dr. Warner's method of instruction of the feeble-minded by gradual advancement. So, for example, the ordinary one-year course is subdivided so that it extends over four years. Great stress is laid on development of physical as well as mental defects by combining a variety of systems especially adapted for this class of pupils. This is the reason why one teacher seldom has more than twenty pupils.

It is obvious that a child whose mental deficiency or nervous peculiarity is but slight will have a better chance of improvement when educated with those of similar mental calibre, than if subjected to hopeless competition with normal children at an ordinary school; or, on the other hand, exposed to the depressing influences of an institution where idiots are received.

Chapter III. is the most instructive and interesting, giving brief pathological sketches of microcephalus, hydrocephalus, Mongol or Kalmuc type, scrofulous cases, birth palsies with athetosis, cretinism (congenital), primarily neurotic, and so on.

The next chapters deal with the etiology, diagnosis, prognosis, and treatment of these various defects. The treatment consists of: *a*, general; *b*, medical and surgical. We have a chapter on educational training and one on industrial training, a chapter on recreation, and finally moral training.

The author sums up by giving his results and conclusions. Condensed as this book is into about 140 pages, it is so full of instruction that each page requires careful reading.

It is rare to find such accurate and excellent illustrations. The reputation of the author will alone insure the success of the book, which is full of points for both pediatric and general practitioner.

FUNCTIONAL AND ORGANIC DISEASES OF THE STOMACH. By SIDNEY MARTIN, M.D. Edinburgh and London: Young J. Pentland. Philadelphia: J. B. Lippincott Co. 1895.

THE author of this excellent book deals first with the anatomy of the stomach and the normal processes occurring in

it, then considers the question of food as a normal dietary, as to digestibility, and as regards its effects of excess or diminution. The pathology of indigestion of food is next dealt with. The newer methods of examination of the gastric contents are minutely described. Under the methods of determining the size and position of the stomach we miss "gastrodiaphany," a method which has been in use for the last few years with great satisfaction. The term "indigestion of food" does not strike us as well chosen, for not always are the abnormal sensations within and around the stomach attributable to real abnormal conditions with regard to the digestion of food within the stomach.

The chapters on the organic diseases of the stomach are full of interest, and the illustrations of the pathological conditions are admirable.

The treatment of chronic gastric catarrh is described by Martin as follows:

"Gastric catarrh, being an inflammation of the stomach, although chronic in its course, must be treated like other inflammatory conditions. For an acute inflammation, rest is essential; for a chronic inflammation, rest is also necessary, and at a certain period of the disease stimulation. Rest can be given to the stomach by means of suitable food, food which the disordered organ can digest. It can also be given medicinally by means of drugs. Although rest is one of the essentials of treatment, and important as allowing the chronic inflammatory condition to resolve, yet if food is to be taken into the organ and digested without discomfort, the disordered stomach must be helped. For in gastric catarrh the inflammatory change leads to a great diminution in function of the organ; a diminished secretion of the gastric juice, especially of the hydrochloric acid, and a diminished motor power of the organ. As regards medicinal treatment, there is no remedy which may be said to be universally beneficial in gastric catarrh, except the mineral acids—nitro-hydrochloric and hydrochloric; these supply the deficiency of the gastric juice, and thus aid the process of digestion when given shortly after meals. For stimulation of the gastric secretion, alkalies before meals are necessary, with or without bitters. Not uncommonly, however, bitters irritate the stomach in gastric catarrh. As sedatives, morphine, opium, codeine, cocaine, and cannabis indica may be used.

"In chronic gastric catarrh, the regulation of the mode of living is of great importance; meals at regular intervals, not late in the evening, a moderate amount of exercise between meals, and a period of rest afterwards are essential. With subacute cases and in the exacerbations of chronic catarrh, bodily and mental rest is essential in the treatment, and, if not obtained, delay in recovery is increased. In chronic cases of catarrh the supplementary methods of treatment are of great use, viz., hygienic treatment, local or general massage, etc. Speaking generally, it may be said that treatment in the early stages of gastric catarrh is very beneficial, as also in those cases where there are attacks at intervals. But in the later stages, where there is degeneration of the mucous membrane, no permanent cure is possible, although much may be done to prevent irritation of the stomach by unsuitable food, and the patient may lead a comparatively healthy life although his gastric digestion is deficient."

AN ATLAS OF THE FERTILIZATION AND KARYOKINESIS OF THE OVUM. By EDMUND B. WILSON, Ph.D., Professor of Invertebrate Zoology in Columbia College, with the Co-operation of EDWARD LEAMING, M.D., F.R.P.S., Instructor in Photography at the College of Physicians and Surgeons, Columbia College. New York and London: Published for the Columbia University Press by Macmillan & Co. 1895. Pp. vii., 32.

THIS admirable work represents the most successful attempt yet made to depict the actual changes which take place in the ovum from the moment of fertilization to the stage at which sixteen segments are formed by the process of cleavage. The eggs of the sea-urchin, artificially fertilized, were preserved at regular intervals, embedded, and sections were photographed and reproduced without reduction. The phototypes are beautifully clear and distinct, representing with a vividness, which in some instances is almost startling, the minute changes in the ovum. The much-abused term "living pictures" finds its scientific application in these triumphs of the photographer's art.

In spite of the technical difficulties which attend the reproduction of the microscopical appearance of protoplasm

under high powers, the plates are sufficiently clear and accurate to satisfy the most fastidious critic. Each plate is briefly but accurately described by the accompanying text. The work is one which will be invaluable to biologists and embryologists.

AN ELEMENTARY COURSE IN EXPERIMENTAL AND ANALYTICAL CHEMISTRY. By JOHN H. LONG, M.S., Sc.D., Professor of Chemistry and Director of the Chemical Laboratories in the Schools of Medicine and Pharmacy of Northwestern University. Chicago: E. H. Colegrove & Co. 1895.

THIS work breaks away from the traditions of most of its predecessors in that it plunges at once into experimental chemistry, the principles of the science being thus taught clinically, as it were, instead of didactically—by example instead of by precept. The student is thus led through a series of simple propositions experimentally established to a comprehension of chemical reactions. The second part is devoted to qualitative analysis, and in the third part the elements of volumetric analysis are set forth. The work is one that should prove of great utility to the student of medicine or to the beginner in chemistry.

OUTLINES OF MATERIA MEDICA AND PHARMACOLOGY. A Text-book for Students. By H. M. BRACKEN, M.D., Professor of Materia Medica, Therapeutics, and Clinical Medicine, University of Minnesota. Philadelphia: P. Blakiston, Son & Co. 1895.

THIS book, the author states, is an amplification of the notes arranged for a lecture course on materia medica at the University of Minnesota. Its purpose is to supply a text-book supplementary to a course of lectures in materia medica. It apparently serves this purpose admirably, and should be useful not only to those whose privilege it is to listen to the author's lectures but to students in other schools as well. It is also a good work of reference for the practitioner who may need occasionally to refresh his mind as to the dose of various preparations of some official or non-official remedy. The doses are given in equivalents of both the metric and the apothecaries' systems.

REMOTE CONSEQUENCES OF THE INJURIES OF NERVES AND THEIR TREATMENT. An Examination of the Present Condition of Wounds Received, with Additional Illustrative Cases. By JOHN K. MITCHELL, M.D. Philadelphia: Lea Brothers & Co. 1895. 8vo, pp. 245.

THIS little work is really a continuation of the valuable contributions of Mitchell, Moorehouse, and Keene, in 1864, and of Mitchell in 1872. Dr. John K. Mitchell has, with great care and labor, traced the histories of many of the cases which were reported in the previous book. He has added a number of new cases, and has thus, in large measure, completed the work begun by the previous authors. The book, necessarily, consists largely of reports of cases, but there are chapters giving proper deductions that have been made, and a final chapter on "Treatment." The book is one which should prove most valuable to both surgeons and neurologists.

PHYSICIANS' VISITING LIST FOR 1896. Philadelphia: Lindsay & Blakiston.

THIS well-known visiting list presents several improvements in the new edition for 1896. More space has been allowed for writing the names and to the "memoranda page;" a column has been added for the "amount" of the weekly visits, and a column for the "ledger page." The lists for seventy-five patients and one hundred patients also have special memoranda page, dated January to June, and July to December.

THE ART OF COMPOUNDING. A Text Book for Students and a Reference Book for Pharmacists at the Prescription Counter. By WILBUR L. SCOVILLE, Ph.G. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut Street. 1895.

THIS work furnishes excellent notes on the subjects of writing and compounding prescriptions. A special chapter is devoted to the subject "Incompatibility," pointing out all the conditions in which two or more different substances—on account of their chemically or physically antagonistic qualities—cannot be compounded. This part of the book is especially important for physicians, and will undoubtedly prove very instructive to its readers.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PREVENTIVE CHOLERA INOCULATION—HAFFKINE'S INDIAN RESULTS—COLOTOMY FOR COLITIS AND DYSENTERY—EARLY CANCER AND CYSTS OF THE BREAST—CHELSEA HOSPITAL DISPUTE—TUBERCULAR OR TUBERCULOUS—SNAKE POISON IMMUNITY PRIORITY—DEFEAT OF QUACKS—HOSPITAL SQUABBLES—PROPOSAL TO EXTEND NOTIFICATION OF DISEASES.

LONDON, December 20, 1895.

PROFESSOR HAFFKINE is now in England, after twenty-nine months of work in India, and at the invitation of the two royal colleges gave a lecture the day before yesterday on his preventive cholera inoculations. You will remember I sent you an account of his former lecture in February, 1893. The record he has now placed before the profession embraces 70,000 injections on 42,179 individuals without a single mishap. The results fall into three groups: (1) Unsuccessful or where no definite conclusion is possible; (2) Slightly favorable to the method; (3) Satisfactory. In Group 1 numerous cases underwent only part of the treatment. Where cholera had most victims and the whole population seemed exposed to it, the result of inoculation was most favorable. Applied during an epidemic it reduced the mortality even in the first few days. The lecturer quoted the opinion of Koch, who says: "The demonstration is complete; the protective power of the inoculation is established finally by the observations collected in India up till now; further perfections and simplifications may be possible, but the main question at issue, the chief part of the problem, is solved by the facts recorded in your report to the government of India." Professor Haffkine intends to return to India and make extensive trial of an antitoxin serum. How far this may aid or defeat his inoculations it is impossible to foresee. He closed with a graceful expression of thanks to all who have assisted him. Sir R. Reynolds, who presided, thanked him for the good work he had done and for coming to give us so lucid an exposition of his method and its results.

The extension of modern surgery has been so rapid that we have ceased to be surprised at any proposal. The physicians, if not the surgeons, of the last generation would perhaps have been more than astonished or awe-struck could they have been present at the Clinical Society this day week. That evening a case was related of membranous colitis in a lady aged thirty, who had been ailing since 1885 with abdominal pain, constipation, discharges of mucus and blood, etc. Eventually, in 1894 tubular casts were passed with intense pain, and she was a complete invalid. Tenderness over the descending colon and sigmoid flexure was present, and a motion on examination seemed composed of a little fecal matter, a great deal of mucus and blood, as well as long tubular casts. As for ten years everything had failed, a right colotomy was undertaken. The bowel was fixed to the surface on May 10, 1895, and opened on the 17th. Three days later the colon was washed out with hot water from the artificial to the natural anus, but membranes had ceased already to be formed. All motions were passed for five weeks through the artificial anus and were quite normal. No purgatives were given. Then the wound was closed, and the bowels were confined with opium for a week. No blood or mucus recurred, and the patient went into the

country in July, feeling better than for years. There, however, she died, and the gentleman who attended her during the last forty hours of her life told the society she had generalized peritonitis and was moribund when he was called in. He found a swelling, on rectal examination, which he thought was probably an enlarged gland which having suppurated, the abscess had burst into the peritoneal cavity. The patient told him there had been no return of the colitis. This case naturally elicited the mention of others in which the operation had been done for dysentery. In one of these the entire mucous surface was found to be studded with polypoid growths, from one to two inches long. The patient improved after the operation and died later from other causes. One case of colitis was described resembling the one operated on, but which got well under small doses of calomel. Some differences of opinion were expressed as to the precise nature of these cases of membranous colitis, and whether the morbid process was not more extensive than the surface of the colon. The differences of the disease from dysentery were also insisted on, especially as to the prospects of operative measures.

The diagnosis and treatment of early cancer and cysts of the breast was the subject at the last meeting of the Medical Society. It was introduced by Mr. Bryant, who divided the cases in which there are difficulties of diagnosis into three groups: 1. Those in which there is some enlargement or thickening of the gland without evidence of anything wrong in the skin, nipple, or lymphatics; 2. Those in which there is a distinct lump, encapsuled or not, inseparable from the gland, with some local conditions, such as flattened or retracted nipple or enlarged axillary glands; 3. Cases in middle age when the gland feels harder than normal, in knots about the size of peas, with at times discharge from the nipple of clear yellow or blood-stained fluid or cheesy matter, whether the lymphatic glands were enlarged or not. In the first group the importance of the diagnosis was pointed out, as the earlier a cancer was removed the better the prospect. A cyst might be mistaken for cancer or even a chronic abscess if connected with lactation. Early exploratory incision was advocated. In Group 2 the possibility of a cyst being present should always be remembered. Cysts had been known to disappear, but so rarely that they ought not to be left to time. The cases of alleged disappearance of sarcoma were probably only cysts. In the Group 3 the point urged was not to conclude too hastily that they were cancerous. Each case must be considered by itself.

Mr. Shield said, in the absence of evidence of malignancy, he assumed a lump to be a cyst. He pointed out that some conditions might render puncture with a trocar deceptive.

Dr. Snow held every mammary tumor in a patient over thirty-four, whether cyst, fibroma, or other, sooner or later would become malignant, and he always removed them. Moreover he had not yet met with a simple cyst. He had, too, seen many cysts connected with malignant disease give a straw-colored or pale fluid, so that the quality of the discharge could not be depended on as a guide. This statement was supported by Mr. Bidwell. A case of difficulty from a sebaceous tumor was mentioned by Mr. Turner, who also discredited the alleged disappearance of sarcomata. Mr. Lockwood said surgeons would save themselves humiliation if they would cut down to a tumor and see what it was. Mr. Bryant, in reply, admitted that cysts might become the seat of malignancy, but that did not justify any one telling patients that cysts were sure to do so.

The discredited board of the Chelsea has taken a step which may not assist in restoring confidence in its proceedings. The board refused arbitration on

LONDON, December 27, 1895.

matters disputed between it and one of the staff, and called a meeting of governors to endorse its action and dismiss the surgeon who asked for arbitration. The meeting took place on Wednesday. At one period of the proceedings there was interruption, with booing, stamping, and noises which must be pronounced disgraceful considering the semi-judicial character of the meeting. An honorary officer was to be dismissed without any charge being formulated against him, except that the board and his colleagues could not get on with him. Mr. Burdett-Coutts resigned rather than be a party to refusing arbitration. Mr. Langman proposed and Dr. Travers seconded that all questions that have arisen should be referred to arbitration, and this was supported by Canon Fleming; but only seventeen votes were given for the proposal and more than one hundred against it. Both the board and staff had threatened to resign unless the dismissal was carried. I cannot congratulate either. The board ought long ago to have retired. The present staff should reflect that they were appointed by this discredited board. Their statement that they could not work with their assailed colleague is as absurd as it is injudicious, considering the many cases in which colleagues are known to be on distant or even unfriendly terms with each other, although discharging their duties at the same hospital. Pity 'tis—but true. As to the merits of this case the meeting affords no information, and the governors appear to have simply voted as the board dictated. We may yet hear more of it.

Tubercular or tuberculous? These adjectives are often confused even by careful writers, and attention has lately been called to the necessity of distinguishing between them. Dr. Fred J. Smith long ago proposed to use the word nodular as the adjective of nodule, which merely means a small lump. This would avoid confusion, and leave the bacillus free to the monopoly of tubercle and both its adjectives.

Professor Ray Lankester has assailed Dr. Fraser, of Edinburgh, rather hastily perhaps, respecting his communications on snake poison, and declares that the honor of the discovery of immunity belongs to Dr. Calmette. Dr. Fraser replies that he has made no claim of priority, and that although his communications have only been preliminary, in which it is not usual to introduce historical notices, he has done justice to Dr. Calmette, of whose researches he has the highest opinion.

Quackery has had some notable reverses lately. John Ferdinand, who signed himself M.D., U.S.A., was proceeded against by the Defence Association for wilfully and falsely assuming the title M.D. He thought the additional letters protected him, but the magistrate decided otherwise and fined him £20 and £10 costs. This Ferdinand issued most offensive advertisements, proclaiming himself "the first physician in the world, the only authority on cancer, rupture, consumption, etc.," stigmatizing hospitals and ordinary doctors, and so on. The only wonder is that any one should believe him, but, as the magistrate remarked, it is the poor and ignorant who are deceived by such practices.

Sherman, the American hernia specialist, has also come to grief in the courts for having obtained 20 guineas by fraudulent representations. He is ordered to refund, with costs. He admitted that in the States he was connected with horse-trotting before taking up the hernia specialty. It is to be hoped other quacks may be brought to book and taught that to pretend to be Americans will not avail them.

Another encouraging case came before the county court as an action for damages against a Manchester cancer quack. The unhappy victim recovered £10, which, with costs, may prove a wholesome lesson to the quack and a warning to the ignorant.

THE Chelsea Hospital committee seems no nearer the end of their troubles. Dr. Watt Black and Mr. Bryant, who were asked to arbitrate, have made public a letter in which they stated that they went to the hospital to ascertain what points were to be submitted to them in order that they might determine whether they could undertake the inquiry. They read the documents, requested Sir A. Borthwick, who attended for the purpose, to state the exact points on which their opinion was desired, and concluded they would not undertake the inquiry unless both parties agreed to abide by their decision. As Sir A. Borthwick represented one party, it seems doubtful whether this proceeding was a wise one, though no one doubts the good faith of the proposed arbitrators. I think either all questions involved should have been referred, or else the two parties should have agreed on the points to be submitted before either communicated with the arbitrators. It is not surprising that Mr. O'Callaghan objected to the arbitrators first meeting a member of the board which desired to eject him. He has been ejected in the manner I reported to you, but it is a most unsatisfactory state of affairs. According to Mr. O'Callaghan the dispute arose from his objection to the house surgeon removing the dressings in his operation cases. If this be so, I think his colleagues will find it no easy matter to justify them in uniting to get rid of him. Surely honorary officers should not be removed except for grave reasons and after proper investigation. Here no complaint is made except the wish of the other officers to get rid of their colleague. This is a sad confession, but it shows the length to which some men will go, and to some extent justifies a remark, made on another case, that "doctors have no common sense." It reminds me of a case I have heard of as occurring lately, but which has not found its way to the journals. Dissatisfied with an election to the staff two members left and took with them the case books of the hospital, containing the cases they had treated. The committee was not a weak, discredited board, and quietly directed its solicitor to recover the books. One man, having consulted his own solicitor, did so; the other refused. The hospital solicitor then informed him that unless he delivered up the book, he must take out a summons against him. This brought the doctor to his senses, for he could scarcely have been in them when he ran the risk of being charged in a police court with appropriating the property of the hospital. This case, however, shows the importance of a committee being strong enough to deal with difficulties in a natural and effective manner. A weak or discredited board in such a case might have hesitated to assert its legal rights and to instruct its solicitor to vindicate them in court.

The propriety of notifying all forms of disease has been forced into a prominence, which is at least premature, by Dr. Newsholme, the able medical officer of health for Brighton. We are not concerned to deny that useful information might be obtained could reliable statistics of the prevalence of all diseases be exacted from the public. But that is impossible. The present system of notification gives great dissatisfaction to many people, and is opposed by not a few doctors, so that even yet it may be repealed. How then can Dr. Newsholme imagine the public will tolerate its extension? One hears already enough about the tyranny of the sanitary officer. What if we had to report to him every ailment we might contract?

Not to be Found.—

Mr. Maximus Miles suffered much from the piles.

And he had a colitis one day;

When the doctor came round, he was not to be found.

For his bowels were running away.

TENDON GRAFTING—A QUESTION OF PRIORITY.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir: My attention has just been called to an article published in the *MEDICAL RECORD* for October 26th last. The article was written by Dr. Samuel E. Milliken, of New York City, and is entitled: "A New Operation for Deformities Following Infantile Paralysis, with Report of a Successful Case."

In this article Dr. Milliken goes straight forward, claiming everything for himself, not mentioning any one's name but his own.

You will imagine my surprise—not to say more—in reading what he had to say when I refer you to an article by myself in the *New York Medical Journal* for October 8, 1892. The title of my article is, "A New Operation for Talipes Valgus and the Enunciation of a New Surgical Principle." In his article Dr. Milliken claims, first, the principle of tendon grafting; second, the special operation of grafting the tendon of the extensor longus pollicis to that of the anterior tibial muscle for the purpose of overcoming a paralytic valgus foot. Both are exactly what I claimed in my article of three years ago. He says: "I believe this to be the first case reported where a healthy muscle has been made to do the work of one which was completely paralyzed, without in any way interfering with its own function." He then goes on, in almost my own words, and comments upon the permanent disabilities in general resulting from infantile paralysis, and then upon the special deformity resulting from paralysis of the anterior tibial muscle. He is then struck by the fact that the extensor pollicis is seldom paralyzed, and is especially strong in his case. Immediately he conceives the idea that it would be a good plan to fasten the pollicis tendon on to that of the anterior tibial and have the good muscle do the work of its crippled neighbor. He then describes the operation he has done which is, in principle, exactly mine. In my article, after describing the same operation as done by myself, with the assistance of Drs. Lewis A. and Reginald H. Sayre, I laid down the general principle of tendon grafting as follows: "However, the important principle of grafting tendons and having a live muscle do the work of a dead one is that which I wish particularly to establish in this article."

Subsequently I exhibited the patient at a meeting of the Orthopaedic Section of the Academy of Medicine in New York. At the same meeting Dr. A. M. Phelps exhibited a similar case. The cases were liberally discussed and published in the transactions of the society.

Has Dr. Milliken a new operation or a new principle? Evidently not. He hardly has new words.

Granting this, was he ignorant of my article, and did he publish his in good faith? If my operation and case had been published in only one medical journal, I should say may be so. But this is not the case. At the time the article was first written, and also at the time the case was reported to the Orthopaedic Section, it was extensively reviewed. Did he see none of these? If he did not, he must be extremely particular about the medical literature he reads.

But this is not all. At that time (and probably yet) Dr. Milliken was one of the editors of a Spanish medical journal, published in New York. He happened into Dr. Sayre's office one day and spoke of having seen my article, and said that he intended reviewing it in his journal, which he did in the following issue. Considering all these things, I must admit I cannot think Dr. Milliken has entirely covered himself with honor.

B. F. PARRISH.

MIDWAY, Ky., December 27, 1895.

AN EARLY TEST FOR GLYCOSURIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In 1892 I made the discovery that if certain articles of food or drink rich in glucose were administered to certain persons and their urine carefully tested during the subsequent twenty-four hours, glucose could be found by use of Prof. Walter Haines' test liquid. On the other hand, the same amount of food or drink, rich in glucose, taken by myself was without result so far as the urine was concerned in its action on the sugar-test liquid. From these experiments I drew the deduction that a predisposition to glycosuria might in some cases be ascertained far in advance of the evil day of diabetes by administration of articles rich in glucose and testing of the urine thereafter. This observation was published in *The Hahnemannian*, for May, 1892.

In a recent number of *THE MEDICAL RECORD*, Dr. von Noorden is given credit for this same discovery. Although not a matter of vital importance to the medical profession, nevertheless I would deem it a favor were you to credit me with priority in this small matter.

CLIFFORD MITCHELL, M.D.

CHICAGO, December 25, 1895.

Medical Items.

Coney Island Beach as a Health Resort.—During the last year the Brooklyn Health Board reports that no less than 14,038 carcasses of decomposing animals, fish, and fowls, scraps of bedding, and lots of garbage were found upon the Coney Island and adjacent beaches, and were buried or burned.

Illuminated Tissues.—A cable dispatch to the *Sun* announces that Professor Routgen, of Bavaria, has discovered in certain rays of light a capital potency the existence of which has heretofore been unknown. Professor Routgen maintains that: "These rays penetrate organic matter and other opaque substances just as ordinary rays penetrate glass." He is reported to be using his discovery to photograph broken limbs and bullets in human bodies.

Provisional Programme for Meeting of the Medical Society of the State of New York.—Albany, January 28 et seq., 1896. **TUESDAY. Morning Session.**—Inaugural address of the President, to be followed by the business sessions, reports of committees, etc. "On Serum Therapy," by Dr. E. H. Wilson, of Hoagland Laboratory, Brooklyn. "Water and its Relations to Disease," by Dr. W. P. Mason, of Troy (late of the Pasteur Institute, Paris). "On Sepsis of the New-Born," by Dr. M. A. Crockett, of Buffalo. "The Question of Puerperal Self-Infection," by Dr. Charles Jewett, of Brooklyn. "A Medico-Legal Note," by Dr. A. Walter Suiter, of Herkimer. "Shall the State Attempt to Control Spread of Tubercular Disease?" by Dr. J. L. Heffron, of Syracuse. **Afternoon Session.**—Discussion: "On Early and Latent Syphilis in Infants and Young Children." Opened by Dr. George T. Elliott, of New York, "Diagnosis and Treatment;" Dr. Ernest Wende, of Buffalo, "Pathology;" Dr. B. Sachs, of New York, "Nervous Manifestations." "Diseases of Intra-Uterine Life." "On the Part of the Mother," by Dr. E. H. Grandin, of New York; "On the Part of the Child," by Dr. P. W. Van Peyma, of Buffalo. Address: "Medical Education of the Future," by Dr. Charles Eliot, President of Harvard University. "On Sloughing Fibroids Complicating Pregnancy," by Dr. M. D. Mann, of Buffalo. **Evening Session.**—"Scorbutus in Infants," by Dr. H. C. MacLane, of Brooklyn. "Treatment of Malignant Disease in So-Called Cancer Institutions," by Dr. Nathan Jacobson, of Syracuse. "Alcoholism and Public Health," by

Dr. H. R. Hopkins, of Buffalo. "On the Evolution of Pathology," illustrated by lantern photographs of those who have developed the science, with illustrations from their works, by Dr. J. H. Hunt, of Brooklyn.

WEDNESDAY. *Morning Session*.—"Abdominal or Vaginal Cœliotomy—Which?" by Dr. J. W. Whitbeck, of Rochester. "Vaginal Hysterectomy without Ligations," by Dr. W. E. Ford, of Utica. "Complications in Abdominal Surgery requiring Intestinal Anastomosis," by Dr. A. Vander Veer, of Albany. "Some Rare Complications of Appendicitis," by Dr. Herman Mynter, of Buffalo. "Treatment of Fractures of the Patella by Continuous Extension, without Confinement in Bed," by Dr. J. D. Bryant, of New York. "Early Diagnosis of Tubercular Kidney," by Dr. Willy Meyer, of New York. "The Improved Cesarean Section," by Dr. H. J. Garrigues, of New York. *Afternoon Session*.—"Congenital Dislocation of the Hip," with exhibition of case successfully operated, by Dr. T. Halstead Meyers, of New York. "Heteroplasty with Celluloid to Cover Defects in the Skull," by Dr. Willy Meyer, of New York. Discussion: "On the Present Status of the Surgery of the Brain." Opened by Drs. E. D. Fisher, A. M. Starr, S. D. Powell ("Surgery of the Skull"), B. Sachs ("Surgical Treatment of Epilepsy"), C. L. Dana ("Craniotomy for Imbecility and Epilepsy"), of New York; Drs. J. W. Putnam and W. C. Krauss, of Buffalo. Address, at 4 P.M.: "Irritation and Counter-Irritation," by Professor William H. Pepper, of Philadelphia. Address: "Deficient Excretion from Kidneys not Organically Diseased, in Some of the Disorders Peculiar to Women," by Professor James H. Etheridge, of Chicago. *Evening Session*.—President's Address: "On the Study of Pathology by Comparative Methods." To be followed by an informal reception in the State Library, and inspection of the new Medical Department of the Library. Annual dinner at the Kenmore House, 9:30 P.M.

THURSDAY.—*Morning Session*.—"Reorganization of the Coroner System," by Dr. W. G. Macdonald, of Albany. "Distinctive Fractures of Railroad Surgery," by Dr. R. S. Harnden, of Waverly. "Diabetes and Acetonuria in Children," by Dr. W. S. Cheesman, of Auburn. "Development of Muscular Atrophy on a Basis of Old Infantile Spinal Paralysis, a Favorable Type," by Dr. W. Browning, of Brooklyn. To be discussed by Dr. C. F. Barber. "The Equilibrium Function of the Ear," by Dr. Gaylord P. Clark, of Syracuse. "On the Surgical Treatment of Retroversions and Retroflexions, with Special Reference to Vaginal Fixation," by Dr. H. N. Vineberg, of New York. "Neuritis Complicating Dislocations of the Shoulder and Elbow," by Dr. M. A. Veeder, of Lyons. "Trephining for Injuries and Diseases of the Cranium," by Dr. W. W. Seymour, of Troy. "Difficult Perineal and Suprapubic Lithotomy," by Dr. W. Hailles, Jr., of Albany. "Abscess of the Frontal Sinus," by Dr. J. P. Creveling, of Auburn. "Some Notes on Trachoma," by Dr. M. L. Foster, of New York. "Tetanoid Hysteria," by Dr. Grace Peckham Murray, of New York. "Treatment of (Edema of the Lungs," by Dr. Louis Faugères Bishop, of New York. "Treatment of Sciatica with Nitroglycerin," by Dr. W. C. Krauss, of Buffalo. "Treatment of Aspiration Pneumonia by Drainage by Invasion," by Dr. W. W. Seymour, of Troy.

The Diaphragm Phenomenon.—Dr. Martius calls attention to the visible movements of the diaphragm, such as have been chiefly described by Litten. This important physical sign has not received the attention which it deserves. During the last three years the author has looked for it in nearly all cases frequenting his polyclinic, and his results completely accord

with those of Litten. This diaphragm phenomenon is really the result of the function of the complementary space formed by the lower part of the pleural sac. The walls of this space touch each other in ordinary breathing, but in deep breathing the diaphragm becomes flattened, and the diaphragmatic pleura is separated from the costal pleura, while the lung enters the space so formed. The sign is thus constituted by the up-and-down movement of the lower margin of the lung in this complementary space during forced breathing. The patient must lie in a horizontal position, with the feet toward a good window light; then in deep inspiration a shallow furrow will be seen travelling downward toward the insertion of the diaphragm, and during expiration it moves upward toward the classical mid-diaphragm position. The limit between the liver and lung can thus be traced. This phenomenon reveals (1) whether the medium position of the diaphragm is the normal one, (2) whether the complementary space is free, and (3) whether the breathing is sufficient. The author says that it may always be seen in normal individuals, except in great obesity and a few other cases. It is more marked on the right than on the left side. The wave follows shortly after the commencement of deep inspiration. It is absent in pleuritic adhesions, in exudations into the pleural cavity, in emphysema, etc. The high position of the diaphragm in cases of peritoneal effusions can be made out.—*Wiener med. Wochenschrift*.

The Medical View of Water Three Centuries Ago.—It needed a very bold man, says *The Hospital*, to resist the medical testimony of three centuries ago against water-drinking. Few writers can be found to say a good word for it. One or two only are concerned to maintain that, "when begun in early life, it may be pretty freely drunk with impunity, and they quote the curious instance given by Sir Thomas Elyot in his "Castle of Health," 1541, of the Cornish men, "many of the poorer sort, which never, or very seldom, drink any other drink, be notwithstanding strong of body, and like and live well until they be of great age." Thomas Cogan, the medical schoolmaster of Manchester fame, confessed in his "Haven of Health," 1589, designed for the use of students, that he knew some who drink cold water at night or fasting in the morning without hurt; and Dr. James Hart, writing about fifty years later, could even claim among his acquaintance "some honorable and worshipful ladies who drink little other drink, and yet enjoy more perfect health than most of them that drink of the strongest." The phenomenon was undeniable, but the natural inference was none the less to be resisted. Sir Thomas Elyot himself is very certain, in spite of the Cornish men, that "there be in water causes of divers diseases, as of swelling of the spleen and liver." He complains oddly also that "it flitteth and swimmeth," and concludes that "to young men, and them that be of hot complexion, it doeth less harm, and sometimes it profiteth, but to them that are feeble, old, and melancholy, it is not convenient." "Water is not wholesome cool by itself for an Englishman" was the verdict of Andrew Borde—monk, physician, bishop, ambassador, and writer on sanitation—as the result of a life's experience. And to quote again the "Englishman's Doctor"—

Both water and small beer, we make no question,
Are enemies to health and good digestion.

But the most formal indictment against water is that of Venner, who, writing in 1622, ponderously pronounces "to dwellers in cold countries it doth very greatly deject their appetites, destroy the natural heat and overthrow the strength of the stomach, and consequently confounding the concoction, is the cause of crudities, fluctuations, and windiness in the body."

INFANTILE INTUSSUSCEPTION—A STUDY OF ONE HUNDRED AND THREE CASES TREATED EITHER BY INTESTINAL DISTENTION OR LAPAROTOMY; AND A REPORT OF TWO CASES.¹

By FREDERICK HOLME WIGGIN, M.D.,

GYNÉCOLOGIST TO THE NEW YORK CITY HOSPITAL, BLACKWELL'S ISLAND.

It is a strange commentary on the advancement made by our science that at the close of this nineteenth century we are met to consider and decide, if we may, upon the comparative merits of the two methods of treatment for intussusception suggested many centuries ago, that of intestinal distention by air or water, by Hippocrates, and that of abdominal section, by Praxagoras. For while since their time much therapeutical ingenuity in the treatment of this disorder has been displayed, our greater pathological knowledge has pushed these remedies aside, and at this time we have only left for consideration a choice between enemata and laparotomy for the relief of this condition.

Some time since a case of infantile intussusception came under the writer's observation, and the questions which were raised led him to more fully investigate this subject. It was found that, while much attention had been given in England to this form of intestinal obstruction, and many cases had been recorded in the medical journals, it had received but scant attention here, and that there were comparatively few recorded cases to be found in American medical literature. The conclusion was reached that either this form of intestinal disorder is of much more frequent occurrence abroad, or that it often fails of recognition here, or that if diagnosticated and treated it is not deemed of sufficient importance to be recorded. When it is realized that intussusception occurring in young infants is practically a hopeless condition when left to nature's care (ninety-eight per cent. of all cases terminating fatally when the immediate or remote effects of sloughing are considered), the importance of the answers to the questions, What is the scientific, and therefore proper, procedure for the relief of these little sufferers? and What is the prospect of the infant's recovery if this method is resorted to? manifests itself, and warrants a careful consideration of the results obtained by one or other of the methods previously alluded to, and a full statement of unrecorded individual experience in the discussion.

In so doing, it is evident that we must determine what foundation exists for the popular belief, both medical and lay, that the method of intestinal distention by air or water is one of safety and that, if unsuccessful, it in no degree interferes with the performance at a later period of laparotomy; or, on the other hand that an abdominal section performed on an infant twelve months of age, or under, must of necessity result fatally, and is, therefore, only to be

resorted to after long delay and the failure of the so-called milder measure to afford permanent relief. Until these questions are finally answered to the satisfaction of the profession at large, it is of the utmost importance that all cases of intussusception, whether treated by one method or the other, and with whatever result, should be fully reported. In this connection, the histories of the two following unreported cases, and the abstracts from the histories collected by the writer from the English and American medical literature since the beginning of the present century, will be of interest.

CASE XIV.—Intussusception successfully treated by enemata. On June 23, 1894, I was requested to prescribe for a female infant, aged four months. It was stated that she had vomited the previous day, that she was costive and very restless. As no further information was given at this time, the diagnosis of indigestion was made, and gray powder ordered. On June 24th, a message was received to the effect that the child had had two movements from the bowels, consequently no haste was made to reach her. When she was seen, the conditions were found to be different from what had been supposed, and the previous history, which was now drawn out, was as follows: The infant had been well from birth. She was nursed, but was given in addition cow's milk, to which sugar and lime water were added. She had been more or less costive from birth. Four days prior to my first visit the mother and child had taken an outing. The infant was fretful, and was in consequence jumped up and down constantly. During the evening she became more restless, and vomited greenish fluid. On June 20th the infant was given castor oil, which was rejected, nothing being retained by her stomach throughout the day. An enema was administered and a movement of the bowels resulted. On June 21st the vomiting persisted, and more oil was given, also another enema, which treatment was followed by a small stool. During the night of June 23d, the restlessness and vomiting became more marked. On June 24th, a physician who was called noticed that the restlessness was caused by colicky pains, and that a stool containing fecal matter and bloody mucus had been passed. The parents insisted that something should be done for the infant's immediate relief, and the physician administered an enema which contained glycerin. Bloody mucus followed, and a tumor, which soon receded, protruded from the anus. When the writer reached the patient, her bodily temperature was 102.4° F., and her pulse was 170. Palpation of the abdomen revealed a cylindrical tumor in the left inguinal and lumbar regions. It could also be felt on rectal examination. The case was diagnosticated to be one of intussusception, probably of the ileo-cæcal variety. The infant was inverted and an enema given consisting of a quart of warm saline solution. The elevation of the reservoir was three feet. The enema was forcibly retained for some minutes, the abdomen meanwhile being palpated (not masséed) to prevent over-distention of the colon. When the liquid was allowed to escape, it was found that the tumor had partly disappeared. One hour later, a small fecal movement occurred, gas escaped from the

¹ Read at the meeting of the New York Academy of Medicine, January 2, 1896.

anus, and a second and larger stool was voided. Dr. J. Lewis Smith now saw the patient, and concurred in the diagnosis and the previous treatment. As the tumor had partially yielded to the former treatment, it was decided to repeat it, the reservoir this time to be raised to four feet, and the abdomen kneaded during the administration of the enema. Under these procedures the tumor disappeared. Two hours later a small faecal movement occurred, and five hours after the disappearance or reduction of the tumor the infant's pulse was 170, and the temperature had fallen to 101° F., its face had regained its natural expression and color, its cry was stronger, and two movements with free escape of gas had occurred. On June 25th, it was noted that the infant had slept during the night, that the tumor had not reappeared, that the temperature was normal, that the abdomen was flaccid, and that three soft, yellow, pasty stools had been passed. The further convalescence was uneventful.

CASE XV.—Intussusception successfully treated by enemata. The writer is indebted for the history of the following case of intussusception to Dr. Frank Overton, of Patchogue, L. I. The doctor reports that during August, 1895, E. H.—, a female infant, aged six and one-half months, came under his observation. She had been well from birth. On the morning of the first day she was visited, she cried violently, and apparently had colicky pains, which were accompanied by a rise of bodily temperature. This condition yielded to treatment. A few weeks later, September 25, 1895, the infant was again seized with severe abdominal pains, cried persistently, and refused to nurse. The mother gave the infant castor oil and paregoric and this treatment was followed by a natural dejection from the bowels. In the evening the child began to vomit and presented a peculiar apathetic appearance, crying continually. Her bodily temperature was 99.5° F. and her pulse was 120. There was no abdominal distention, and gray powder was ordered. Early on the morning of September 26th, she voided two ounces of blood and later a smaller quantity. She now cried constantly and vomited frequently; her temperature was 102° F., her pulse was 140, and intussusception was suspected. At 7 A.M. her temperature was 103° F. and her pulse had risen to 180. At 9 A.M. a consultation was held. Abdominal palpation revealed the fact that there was no distention of the bowels, but that there was a localized point of tenderness in the right side just below the umbilicus, and there a small tumor was finally felt. A reservoir was filled with warm saline solution and raised five feet above the infant's body, which was partly inverted. All the water possible without causing over-distention of the colon was injected into the bowel and forcibly retained. Massage was also applied to the abdominal wall. The child became quiet, and after five minutes had elapsed the water was allowed to escape. The tumor could now only be felt with difficulty, and the previously described procedure was repeated. After the escape of the second enema a large faecal movement was voided, containing bloody mucus. The tumor had now disappeared. The change in the patient's countenance was magical; the vomiting ceased, and she fell asleep. During the succeeding hours she nursed freely. On September 27th it was noted that the infant had slept all night, that her temperature was normal, and that a large faecal movement which contained neither blood nor mucus was voided. Convalescence was uneventful.

Cases of Infantile Intussusception Successfully Treated by Enemata or Inflation.—Table No. I.

CASE I.—In the *British Medical Journal* for 1894, vol. i., p. 345, is recorded, from notes furnished Mr. Barker by the University College Hospital, a case of intussusception of the ileo-caecal variety which occurred

during 1879 in a male infant, aged six months. It was admitted to the hospital thirty-one hours after the beginning of the attack. Abdominal palpation revealed a tumor. Injections of air and water were made into the bowel, causing the disappearance of the tumor, which did not again appear.

CASE II.—Dr. Andrew records, in the St. Bartholomew's Hospital Reports for 1892, a case of intussusception occurring in a male infant, aged four months, which came under observation on the second day of the disorder. An enema of eight ounces of water was administered. This procedure caused the apparent disappearance of the tumor, which reappeared the next day. Enemata were given hourly for nine hours, finally causing the tumor to disappear permanently.

CASE III.—Sir William Savory records, in the St. Bartholomew's Hospital Reports for 1892, a case of intussusception occurring in a female infant, twelve months of age, which came under observation on the first day. An enema consisting of a pint of warm milk was administered within nine hours after the disorder manifested itself. This treatment was followed by the apparent disappearance of the tumor, which, however, reappeared the next day. The enema was repeated with satisfactory results, and there was no recurrence of the trouble.

CASE IV.—Mr. Beck records, in the *British Medical Journal* for 1894, vol. i., p. 346, a case of intussusception of the ileo-caecal variety which occurred during 1885, in a male infant, aged five months. The case came under observation on the first day. Abdominal palpation revealed a tumor. Under chloroform narcosis an enema was administered, and while this was being done the tumor was manipulated between the finger and thumb. Reduction followed, and there was no further trouble.

CASE V.—In the *British Medical Journal* for 1894, vol. i., p. 345, is recorded from notes furnished Mr. Barker by the University College Hospital, London, a case of intussusception of the ileo-caecal variety, which occurred during 1888 in a male infant, aged seven months, which came under observation six hours after the disorder began. Injections of air and water were tried with successful results.

CASE VI.—In the *British Medical Journal* for 1894, vol. i., p. 345, a case of intussusception of the ileo-caecal variety is recorded from the notes of the University College Hospital, London, as having occurred in a male infant, aged nine months, during 1888, and which came under observation on the first day. Under chloroform narcosis the bowel was inflated with air, the abdomen being meanwhile manipulated. This treatment resulted in the gradual disappearance of the tumor and of all the symptoms of the disorder.

CASE VII.—In the *British Medical Journal* for 1894, vol. i., p. 346, the following case of intussusception of the ileo-caecal variety occurring in a male infant, aged six months, is credited to the University College Hospital. The infant came under observation within the first twelve hours of the disorder. Abdominal and rectal examination revealed a tumor. Manipulation followed by enemata of air and water were tried with partial success, but the tumor soon reappeared. Reduction was finally effected by an enema, the reservoir being elevated three feet above the patient's body.

CASE VIII.—Mr. Gee records, in the *British Medical Journal* for 1894, vol. i., pp. 345 and 346, a case of intussusception which occurred during 1890, in a male infant, aged nine months. It came under observation on the second day. Abdominal and rectal examination revealed a tumor. Enemata were administered with successful results.

CASE IX.—Dr. A. Jeffery Wood reports, in the *Australian Medical Journal*, 1894, vol. i., p. 287, a case

of intussusception occurring in a male infant, aged six months, which came under observation on the second day. The infant, after being anesthetized, was partly inverted and the bowel distended with air, deep massage being meanwhile employed. Under this treatment the tumor disappeared. One quart of warm water was injected into the bowel. This was followed one hour later by a stool. During the night the infant had seven dejections from the bowels, none of which contained blood. The disorder did not recur.

CASE X.—University College Hospital reports, in the *British Medical Journal* for 1894, vol. i., p. 346, a case of intussusception of the ileo-cæcal variety, occurring during 1892, in a male infant, aged ten months. Abdominal examination revealed a tumor. The bowel protruded from the anal orifice. Inflation was tried with success, the tumor disappeared, and the infant recovered.

CASE XI.—Dr. Beeston records, in the *Australasian Medical Gazette* for 1893, vol. ii., p. 373, a case of intussusception occurring in a male infant, aged seven months, which came under observation on the second day. Insufflations of air were tried, but proved unsuccessful. On the fourth day the patient had copious stools, and passed a piece of fleshy-looking matter having a putrid odor. There was no further trouble.

CASE XII.—Mr. D. J. Caddy records, in the *British Medical Journal* for 1894, vol. i., p. 126, a case of ileo-cæcal intussusception occurring in a female infant, aged six months, which came under observation on the first day. Abdominal palpation revealed a tumor. The infant passed blood from the anus, and vomited soon after it was first seen. Water was forcibly injected into the rectum, causing the apparent disappearance of the tumor. Soon after, one ounce of blood escaped from the rectum. The next morning the infant was again seized with colicky pains, and cried violently. She passed more blood, and a further trial of enemata under increased pressure was made, with a successful result.

CASE XIII.—Dr. Williams records, in the *Lancet* for 1894, vol. i., page 537, a case of intussusception occurring in a male infant, aged eight months, which came under observation on the first day, giving a history of intestinal derangement for one week. Examination of the abdomen showed it to be much distended, and palpation revealed a tumor. Inversion combined with massage and an enema followed by insufflation of air were tried, all to no purpose. Two basins were procured, each containing eight ounces of warm water. In one a drachm and a half of citric acid was placed, and in the other two drachms of bicarbonate of soda. The acid solution was thrown into the bowel through a catheter, and was followed by the alkaline solution. The catheter was quickly withdrawn, and the nates held together for several minutes. The tumor could now no longer be felt, the vomiting ceased, and a natural defecation from the bowels occurred two days later.

CASE XVI.—Dr. Ruff reports, in the *Medical News*, vol. xl., p. 299, a case of intussusception occurring in a male infant, aged seventeen days, which came under observation five hours after the first seizure. The infant was partly inverted, and an enema of water was given and forcibly retained for five minutes. This proving unsuccessful, inflation was tried, and then alternating injections of air and water at intervals for two hours. This treatment proving ineffectual, chloroform was administered, and abdominal massage practised without benefit. Morphine was given, then alternating injections of air and water at intervals for six hours. This treatment was followed two hours later by a stool, and four hours after this occurred the infant started suddenly, and the tumor could no longer be felt. There was no reappearance of the disorder.

Cases of Infantile Intussusception Unsuccessfully Treated by Enemata or Inflation.—Table No. 2. CASES I. to VIII.—Mr. Gorham, in Guy's Hospital Reports, vol. iii., p. 330, records eight cases of intussusception occurring in infants whose ages ranged from three to eleven months. They were all treated in the first place by purgatives, and, this treatment proving ineffectual, by enemata. The cases all terminated fatally.

CASE X.—Dr. F. Taylor and Mr. Golding Bird report, in the Transactions of the Clinical Society of London, vol. xvi., p. 67, a case of intussusception of the ileo-cæcal variety occurring during 1881, in an infant, aged eight months, which came under observation on the first day. Abdominal and rectal examination revealed a tumor, and there were blood and mucus on the diaper. The bowel was distended with air, and the tumor under this treatment apparently disappeared only to return some hours later. Chloroform was then administered, and inflation again tried with increased pressure, but without avail, as the infant soon died. The necropsy revealed the fact that the invaginated bowel remained unreduced. Forcible inflation with air was tried (without result), and then with water, which reduced the ileum but left the colon inverted. This proved also to be gangrenous. Under the injection of water the peritoneal and muscular coats of the bowel gave way at several points, leaving the mucous coat intact.

CASE XI.—Mr. Andrews records, in the St. Bartholomew's Reports for 1892, a case of intussusception which occurred during 1881, in an infant, aged four months, which came under observation on the third day. Four enemata were administered. After the last one the tumor could not be felt. On the following day the infant died. The necropsy revealed the fact that the invaginated bowel remained unreduced. No evidence of peritonitis existed.

CASE XII.—Mr. Barker records, in the *British Medical Journal* for 1894, vol. i., p. 345, a case of intussusception of the ileo-cæcal variety, occurring in a female infant, aged four months, which came under observation during the first twenty-eight hours. Inversion and enemata of air and water were tried, causing the apparent reduction of the tumor, but it reappeared nine hours later. The enemata were repeated with apparent success. Two hours later the tumor could again be made out, and it was again apparently reduced by enema. The infant collapsed and died. The necropsy revealed the fact that the invaginated bowel had never been completely reduced, and that it was gangrenous.

CASE XIII.—Mr. Cripps records, in St. Bartholomew's Reports for 1892, pp. 97-111, a case of intussusception occurring during 1884, in a male infant, aged four months, who came under observation on the fourth day. Under chloroform narcosis, an enema consisting of one and a half pints of water was administered. While this was being accomplished, the infant vomited, inspired vomited material, and died. The necropsy revealed two lacerations of the bowel, probably caused by the enema.

CASE XIV.—Mr. Baker records, in St. Bartholomew's Reports for 1892, p. 97, a case of intussusception occurring during 1884, in a male infant, aged seven months, which came under observation on the eighth day. Two enemata were administered, and the last apparently reduced the invagination, as the tumor could no longer be felt. Five hours later, however, the infant died. No necropsy was made.

CASE XV.—Mr. Andrews records, in St. Bartholomew's Hospital Reports for 1892, a case of intussusception occurring during 1886, in a male infant, aged four months, which came under observation on the fourth day. Six enemata of oil and two of milk were

administered. This treatment was followed by the infant's death. The necropsy revealed the fact that the invagination had been only partially reduced.

CASE XVI.—Mr. Mortimer reports, in the *Lancet* for 1891, vol. i., pp. 1,145 and 1,146, a case of intussusception occurring in an infant, aged eight months, which came under observation on the fourth day. Under chloroform narcosis, abdominal palpation revealed a tumor. This procedure was followed by collapse. The infant was stimulated, and two enemata, each consisting of about two ounces of fluid, were administered. After the last one had escaped, the tumor could no longer be felt. Opiates were given, and for two days the only symptoms were occasional expressions of pain and increasing abdominal distention. At the end of this time, vomiting recommenced, and the tumor reappeared. Chloroform was administered a second time, and ten ounces of water were injected into the bowel, the reservoir being raised three feet. Following this three enemata were administered, and the tumor partially disappeared. The next day a pint of water was injected at a lower pressure than previously, and it was repeated on the succeeding day. A few hours later the infant expired. The necropsy revealed three points of rupture in the descending colon.

CASE XVII.—J. Aitken Clark, in the *Edinburgh Hospital Reports*, 1894, page 239, records a case of intussusception occurring on November 22, 1892, in a male infant, aged five months, which came under observation on the second day. Opium and enemata were administered frequently without result. It died on the sixth day of the disease. The necropsy revealed the fact that a double intussusception remained unreduced, one at the splenic flexure, and the other at the sigmoid flexure of the colon.

CASE XVIII.—Dr. Edward Deanesley records, in the *Lancet* for 1894, vol. i., p. 601, a case of intussusception of the ileo-cæcal variety occurring in a female infant, aged seven months, which came under observation on the fifth day after the bowel protruded from the anal orifice. A history of a month's previous illness was given. Two days prior to the infant's admission to the hospital, the mother returned the bowel inside the anus, and gave the infant castor oil. This treatment aggravated the symptoms, the bowel again appeared outside of the anus, and a small stool containing blood was passed. The bowel was returned with ease inside the anus, and on pushing it up the ordinary abdominal tumor was recognized. An anæsthetic was administered, and was followed by an enema of one pint of water having a head of two feet, the abdomen being meanwhile masséed. After the fluid escaped the tumor could no longer be felt. The bowels moved twice. The next day, as the infant was drowsy, the opiate was discontinued. Toward evening the infant vomited, and during the succeeding twenty-four hours the bowel once more protruded. Under chloroform narcosis it was reduced by enema, but it reappeared the following day, when reduction was again apparently effected by enema. Twenty-four hours later death occurred. Necropsy revealed the fact that the invagination remained unreduced, and that its reduction could easily have been effected by laparotomy.

CASE XIX.—Mr. Winter reports, in the *Lancet*, vol. i., p. 600, a case of intussusception of the ileo-cæcal variety occurring in a female infant, aged seven months, which came under observation on the second day of the disorder. At this time a tumor protruded from the anus. Under chloroform narcosis one pint of water was injected into the bowel, the receptacle containing it being raised two feet, and the abdomen meanwhile being masséed. Under this treatment the tumor disappeared. The next day a normal stool

occurred. Two days later the bowel again protruded. Chloroform was again employed, a second enema was administered, and reduction of the tumor was apparently effected. The following day the bowel again protruded. Under chloroform narcosis an enema was given with apparently satisfactory results, but on the succeeding day the infant died. At the necropsy it was found that the bowel protruded from the anus, as it had done prior to death. The intussusception was found to lie in the exact centre of the abdominal cavity. It lay alongside the spine, was closely attached to it by the meso-colon, and it passed straight downward from about the third lumbar vertebra to the pelvic outlet. The protruding mass was returned inside the rectum, and an attempt made to reduce it from above by pulling the entering part of the ileum, but it was impossible to do so. The reduction was ultimately effected with ease by encircling the bowel below the apex of the intussusception with the thumb and finger, and holding the bowel a few inches lower down. The apex was then pushed up with the fingers. No adhesions had formed between the opposed peritoneal surfaces of the entering and returning layers.

CASE XX.—J. Aitken Clark reports, in the *Edinburgh Hospital Reports* for 1894, p. 239, a case of intussusception of the ileo-cæcal variety, occurring during January, 1894, in a male infant, aged nine months, which came under observation on the third day. The infant was inverted and enemata administered at short intervals, but without result, death occurring on the evening of the third day. The necropsy revealed the fact that the invaginated bowel remained unreduced.

CASES IX., XXI., XXII.—Mr. Hutchinson cites (*Lancet*, 1891, vol. i., p. 1,146) three cases of intussusception within his own experience, where infants were treated by enemata of air and water, which treatment was followed by death. The necropsies revealed the fact that the invaginations in all cases remained unreduced.

CASE XXIII.—In the *Lancet* for 1891, vol. i., p. 1,144, Mr. J. D. Mortimer records a case of intussusception occurring in an infant, aged three months, which came under observation on the first day of the disease. The infant had vomited and passed blood from the anus. Rectal examination revealed a tumor. The bowel was inflated with air, and the tumor disappeared. Opiates were given. Some hours later the vomiting recommenced, and the abdomen became distended. Collapse followed, and the infant died. The necropsy revealed the fact that the invagination had not been reduced. A tube was tied into the rectum and connected with a reservoir containing water, and elevated two feet above the cadaver. The water was allowed to pass into the intestinal canal. In a few minutes the invagination was almost reduced, but about one inch of the ileum, the cæcum, and part of the vermiform appendix remained tightly ensheathed in the colon. After fifteen minutes of sustained pressure, the reservoir was raised from three to four feet, and a slight further reduction of the invaginated portion of bowel took place. This went no further, and in four minutes the colon ruptured in three places, just below the intussusceptum. The invagination, however, was readily reduced by manipulation from below without obvious damage. There was a little lymph on the peritoneal surfaces of the cæcum, and its mucous membrane was infiltrated and slightly shreddy. The valve was much swollen, and by its obstruction would probably have caused rupture at the moment of complete reduction had this been effected by the enema.

Post-Mortem Experiments.—Mr. Mole describes, in the *Bristol Medico-Chirurgical Journal*, 1894, p.

65, some experiments made on infantile cadavers. He found that when one and one-half pints of water had been injected into the bowel under a pressure of one and one-half pounds to the square inch (three feet) the liquid passed through the ileo-cæcal valve; also, that air could be made to pass the same point. His conclusions were: (1) That no harm can be done healthy intestine by enemata of fluids under a moderate pressure; (2) that hydrostatic pressure is more uniform, and therefore less likely to cause rupture of the bowel; (3) that the part most likely to be injured by over-distention is the transverse colon.

Cases of Infantile Intussusception Unsuccessfully Treated by Laparotomy.—Table No. 3. CASE I.—Ashhurst, in the course of an article entitled "The History of Laparotomy for Intussusception," *American Journal of the Medical Sciences*, vol. lxviii., p. 54, states that the first laparotomy performed on an infant for the relief of an intussusception was by Gerson, and reported by Hackman, of Hamburg. The operation was performed on September 18, 1828. The subject was a male infant, aged twelve weeks. An oblique incision was made in the direction of Poupart's ligament on the left side. While effort was being made to reduce the invagination the bowel gave way at a gangrenous point, the operation was abandoned, and the infant expired.

CASE II.—In the *American Journal of the Medical Sciences*, vol. lxviii., p. 54, Sir Spencer Wells reports a case of intussusception occurring in an infant, aged four months, which came under observation on the third day of the disease. The operation was performed on the following day, when the infant was in collapse. It died five hours later.

CASE III.—Mr. Barker credits Busch, in the *Lancet*, 1888, vol. ii., p. 262, with a case of intussusception occurring during 1869 in a male infant, aged seven months, which came under observation on the fourth day of the acute illness. Laparotomy was performed; the invaginated gut proved to be irreducible, therefore an artificial anus was made. Death occurred eight days later.

CASE IV.—Ashhurst credits Professor Weinlechner, of Vienna, in the *American Journal of the Medical Sciences*, vol. lxviii., p. 54, with a case of intussusception of the ileo-cæcal variety, which occurred during 1871 in a female infant, aged six months. Laparotomy was performed on the fourth day, and was followed by death a few hours later.

CASE V.—In the *Lancet*, 1888, vol. ii., p. 262, a case of intussusception of the ileo-cæcal variety occurring during 1873 in an infant, aged five months, is credited by Barker to Duncan. A history of several days' previous illness was given, but the day upon which the infant came under observation is not noted. Laparotomy was performed, but proved unsuccessful, death ensuing on the following day.

CASE VI.—Mr. Jonathan Hutchinson records, in the *Lancet* for 1875, vol. ii., p. 877, a case of intussusception of the ileo-cæcal variety occurring in an infant, aged six months, which came under observation on the third day. Enemata had previously been administered without result. The patient was failing, therefore laparotomy was performed at once. The invaginated portion of bowel was reduced with difficulty. The case terminated fatally six hours later.

CASE VII.—Mr. Barker credits Howse, in the *Lancet* for 1888, vol. ii., p. 262, with a case of intussusception of the ileo-cæcal variety occurring during 1876 in an infant, aged five months, which came under observation after a month's indisposition. Laparotomy was performed. Death ensued a few hours later.

CASES VIII., XIII.—In the *Lancet* for 1888, vol. ii., p. 262, Stage is credited with two cases of intussusception, one occurring during 1876 and the other in

1880. The first was a female infant, aged six months, which came under observation on the second day. Laparotomy was performed, and death ensued a few hours later. The second was a male infant, aged three months, which came under observation on the first day. Laparotomy was performed, and was followed by death two and one-half days later.

CASE IX.—Mr. Smith records, in the St. Bartholomew's Hospital Reports for 1892, vol. xxviii., p. 106, a case of intussusception of the ileo-cæcal variety occurring during 1877 in a male infant, aged eight months, which came under observation on the fourth day, giving a history of two days' previous illness, the chief symptoms of which were abdominal pain, vomiting, and the passage of blood from the anal orifice. No tumor could be felt on making either abdominal or rectal examination. Inflation on the second day had afforded slight relief. It was tried again on the third day, and followed on the fourth day by enemata, which seemed to give some relief. Laparotomy was, however, performed on the fifth day. There were no evidences present of peritonitis, although the ileum, which had slipped through the ileo-cæcal valve, was gangrenous. This portion of gut was excised, and an anastomosis effected. Death followed five hours later.

CASE X.—Mr. Beck is credited, in the *British Medical Journal* for 1894, vol. i., p. 346, with a case of intussusception of the ileo-cæcal variety occurring during 1877 in a female infant, aged eight months, which came under observation five and one-half hours after the beginning of the attack. Repeated enemata of oil and air were administered without result, and twenty-six hours from the beginning of the disorder laparotomy was performed. The invaginated bowel, while deeply congested, was easily reduced. The operation, however, was unsuccessful, being followed by death from septic peritonitis.

CASE XI.—The *Lancet* for 1888, vol. ii., p. 262, credits Sands with a case of intussusception of the ileo-cæcal variety occurring during 1878 in a male infant, aged six and one-half months, which came under observation on the second day. Laparotomy was performed, and was followed by death four hours later.

CASE XII.—The *Lancet* for 1888, vol. ii., p. 262, credits Corley with a case of intussusception of the colic variety, occurring during 1879 in an infant, aged nine months, which came under observation after several days' illness. Laparotomy was performed, and was followed by death four hours later.

CASE XIV.—Mr. R. J. Godlee reports, in the Transactions of the Clinical Society of London, vol. xvi., p. 67, a case of intussusception of the ileo-cæcal variety occurring in 1882 in an infant, aged fourteen weeks. Laparotomy was performed, and the invagination was reduced with difficulty. The infant died, and the necropsy revealed the fact that the reduction at the time of operation was only partial.

CASE XV.—Mr. Walsham is credited, in the St. Bartholomew's Hospital Reports for 1892, pp. 97-111, with a case of intussusception occurring during 1882 in a male infant, aged seven months, which came under observation on the third day. Distention of the bowel with air and water was tried. This treatment proving unsuccessful, laparotomy was performed, notwithstanding the fact that peritonitis existed. The invaginated bowel was reduced with difficulty. The operation was followed by death.

CASE XVI.—Marsh records, in the St. Bartholomew's Reports for 1892, a case of intussusception occurring during 1882 in a female infant, aged eight months, which came under observation on the second day. Inflation with air was employed, but without success. Laparotomy was then performed, and the invaginated bowel was easily reduced. Death ensued on the following day.

ONE HUNDRED AND THREE CASES OF INFANTILE INTUSSUSCEPTION TREATED EITHER BY INTESTINAL DISTENTION OR LAPAROTOMY.

By FREDERICK HOLME WIGGIN, M.D.

The percentage of mortality of laparotomy performed since 1890 for infantile intussusception is 22.2%.

CASE XVII.—In the *Lancet* for 1888, vol. ii., p. 262, Braun is credited with a case of intussusception of the ileo-colic variety, occurring during 1882 in a male infant, aged three months, which came under observation on the fifth day. Laparotomy was performed, and as the invagination could not be reduced, it was excised, and an artificial anus made. Death ensued one hour later.

CASE XVIII.—Drs. Kudlich and Jacobi record, in the *MEDICAL RECORD*, vol. xxi., p. 299, a case of intussusception occurring during 1882 in a female, aged two months, which came under observation eighteen hours after the onset. Enemata and massage were first unsuccessfully employed, and were followed by laparotomy. Great difficulty was experienced in reducing the invaginated bowel, and the operation was followed by death.

CASE XX.—Mr. R. J. Godlee reports, in the *Transactions of the Clinical Society*, vol. xvi., p. 67, a case of intussusception occurring during 1883 in an infant, aged seven months, which came under observation on the third day. Abdominal palpation revealed a tumor in the right umbilical region. Enemata of air and water were first tried without success. Laparotomy was performed under chloroform narcosis. The invagination, which proved to be of the ileo-caecal variety, was reduced with some difficulty. The operation was followed by death, due to septic peritonitis.

CASE XXI.—In the *Lancet* for 1888, vol. ii., p. 262, Symonds is credited with two cases of infantile intussusception. The cases occurred during 1884. The first was of the ileo-caecal variety, and occurred in a male infant, aged five months. It came under observation on the seventh day of acute illness, following thirteen days of indisposition. Laparotomy was performed, and was followed by death.

CASE XXII.—The second case occurred in a female infant, aged six months, and came under observation on the twentieth day of subacute illness. Laparotomy was performed, and was also followed by death.

CASE XXIII.—Mr. Beck records, in the *British Medical Journal* for 1891, vol. i., p. 346, a case of intussusception of the ileo-caecal variety occurring during 1885, in a male infant, aged five months, which came under observation fifty-five hours after the onset. Abdominal palpation revealed a tumor. Injections of air and water were tried, but proving unsuccessful, laparotomy was performed. The invagination proved irreducible, and the operation was abandoned. Death soon occurred.

CASE XXIV.—Mr. Edmund Owen reports, in the *British Medical Journal* for 1885, vol. i., p. 1,201, a case of intussusception occurring in a female infant on the day of its birth, which came under observation on the second day. Prior to this, castor oil had been given. Digital exploration of the rectum proved the bowel to be pervious. Under chloroform narcosis an enema was administered, but without result. On the following day (third) the enema was repeated, but without affording relief. Laparotomy was performed, and the first piece of small intestine which presented in the wound was seized, and an artificial anus made. No attempt was made to find the invaginated portion of intestine. The infant survived the enterectomy six days, dying on the ninth day after its birth.

CASE XXV.—In the *British Medical Journal* for 1891, vol. i., p. 346, Horseley is credited with two cases of infantile intussusception, occurring during 1885. The first was that of a male infant, aged four months, was of the ileo-caecal variety, and came under observation on the fourth day. Laparotomy was performed, and the intussusception proving irreducible, it was excised, and an artificial anus was made. Death soon followed the operation.

CASE XXVI.—The second also occurred in a male infant, and was of the ileo-caecal variety. It came under observation nineteen hours after the onset. Laparotomy was performed. Death followed thirty hours later.

CASE XXVII.—In the *Lancet* for 1887, vol. i., p. 1,179, are recorded two cases, credited to Jacobson, of intussusception. The first occurred in 1886, in a male infant, aged five months, which came under observation with a history of three weeks' previous illness. Laparotomy was performed, and the invaginated portion of bowel was found to be partly gangrenous and irreducible. The infant's condition at this time was fairly good, but after the excision of the invaginated gut it became very bad, and the patient soon expired.

CASE XXVIII.—The second case occurred in an infant, aged eleven months, which came under observation with a history of a month's previous illness. Laparotomy was performed, and the invaginated portion of bowel was found to be irreducible. The operation was concluded without resection of the tumor, in the hope that spontaneous cure would result by sloughing. Death ensued twenty-four hours later.

CASE XXIX.—Dr. Van Arsdale, in the *Annals of Surgery*, vol. xx., pp. 418 and 419, records the fact that he had resorted to laparotomy three times in the treatment of infantile intussusception. The operation was followed by death in all of the cases. Since this report the doctor has kindly furnished the writer with additional details of these cases. They occurred about 1887, in infants under six months of age. In one case peritonitis existed at the time of operation, and the bowels were much distended. The trouble was not satisfactorily located, and the operation was incomplete.

CASE XXX.—In another of the cases the intussusception was irreducible, and an artificial anus was made.

CASE XXXI.—The same treatment was adopted in the third case.

CASE XXXII.—Mr. Pick records, in the *Lancet* for 1891, vol. i., p. 1,313, a case of intussusception of the enteric variety occurring during 1887, in an infant, aged six months, which came under observation with a history of three weeks' previous indisposition, and the last two days of which had been acute. Abdominal examination revealed a tumor in the left inguinal and lumbar regions. The infant was given chloroform, inverted, and the bowel inflated with air. Under this pressure the fingers which had been placed on the abdomen over the tumor felt it suddenly melt away. Opiates were administered, but about nine hours later the infant did not appear as well and an enema of oil was administered. On the following morning the abdomen was tender and somewhat distended. A few hours later, Mr. Pick found the infant collapsed, and performed laparotomy. No invagination was found, but a piece of small intestine, six inches in length, which was collapsed and showed signs of having been constricted at either end, it looking paralyzed. The bowel immediately below this portion of gut was also empty and collapsed. The operation was well borne, but soon after the infant suddenly collapsed, and shortly thereafter died. Mr. Pick's explanation of this condition was that the first portion of gut found collapsed had been involved in the intussusception, that it had been reduced by the air pressure, but that the gut had been so long constricted that it could not recover itself after its release; therefore the symptoms continued unchanged after the reduction.

CASE XXXIII.—In the *St. Bartholomew's Hospital Reports* for 1892, Mr. Walsham is credited with a case of intussusception occurring during 1888, in an infant, aged eight months, which came under observation on the first day. Laparotomy was performed, and at the point of beginning of the invagination a small sessile

tumor was found. Death followed the operation, twenty-four hours later.

CASE XXXIV.—Mr. Marsh records, in the *St. Bartholomew's Hospital Reports* for 1892, p. 111, a case of intussusception of the ileo-caecal variety, occurring during 1889, in a male infant, aged four months, which came under observation on the fourth day. A previous history of abdominal pain, vomiting, and passage of watery stools, which contained blood, was given. Abdominal and rectal examination revealed a tumor. Laparotomy was performed, and difficulty was experienced in reducing the invaginated bowel. Death ensued a few hours later from exhaustion.

CASE XXXV.—Mr. Cripps records, in the *St. Bartholomew's Hospital Reports* for 1892, vol. xxviii., p. 111, a case of intussusception of the ileo-caecal variety, occurring during 1890, in a male infant, aged five months, which came under observation on the third day. A previous history of several days' illness was given, the chief symptoms of which were abdominal pain, vomiting, and the passage of blood-stained mucus from the bowel. Enemata of warm water failed twice to reduce the invagination. Abdominal and rectal examination revealed a tumor. Laparotomy was performed, and the gut was apparently reduced, but death occurred two hours later. The necropsy revealed the fact that the intussusception had been only partially reduced. There was no evidence of peritonitis.

CASE XXXVI.—Mr. Walsham is credited, in the *St. Bartholomew's Hospital Reports* for 1892, p. 111, with a case of intussusception occurring during 1890, in a male infant, nine months of age, which came under observation on the third day. Laparotomy was performed. The invaginated bowel was easily reduced. Death followed the operation. The necropsy revealed the fact that there was a small perforation in the transverse colon, and that death was due to septic peritonitis.

CASE XXXVII.—Mr. A. E. Barker records, in the *Lancet* for 1892, vol. i., p. 80, a case of intussusception occurring in an infant, aged four months, during 1891, which came under observation on the fourth day. An unsuccessful attempt to reduce the intussusception by inflation had been made. On examination the infant was found to be collapsed. It emitted a gangrenous odor. Under chloroform narcosis, rectal and abdominal palpation revealed a tumor. Laparotomy was performed. The gut was found to be gangrenous and was excised, and the divided ends joined. Death ensued ten hours later. The necropsy proved the sutures of the bowel to be firm, and they resisted strong pressure of water without leaking.

CASE XXXVIII.—Mr. F. J. Sheppard records, in the *Lancet* for 1892, vol. ii., page 1,155, a case of intussusception of the ileo-caecal variety, occurring in an infant, aged seven months, which came under observation on the second day. Examination at this time revealed a dark-colored protrusion from the anus. Laparotomy was performed under chloroform narcosis. On account of the intestinal distention the invaginated gut was found with difficulty and reduced only after the intestine had been incised. The operation was followed by the infant's death, three hours later.

CASE XXXIX.—Mr. Paul Bush reports, in the *Bristol Medico-Chirurgical Journal*, 1894, p. 6, a case of intussusception occurring in an infant, aged four months, which came under observation on the third day of the disease. Enemata were administered without success. Laparotomy was performed. The intussusception proved to be of the enteric variety and irreducible. The tumor was excised and an artificial anus made. Peritonitis ensued, and the infant died twenty-four hours later.

CASE XL.—Dr. Abbé reported, in the *Annals of Surgery*, vol. xx., p. 419, a case of intussusception oc-

curing during 1893, which came under observation sixteen hours after the onset. Laparotomy was performed. The invaginated bowel was reduced with much difficulty on account of the strong adhesions which had already formed. Death followed the operation twenty-four hours later.

CASE XLI.—Mr. A. E. Barker records, in the *British Medical Journal* for 1894, vol. ii., p. 1,237, a case of intussusception occurring in a male infant, aged four months, which came under observation on the third day. Abdominal and rectal palpation revealed a tumor, and blood and mucus were passed from the anal orifice. Under chloroform narcosis warm water was injected into the bowel from a reservoir raised three feet above the patient's body. When five ounces had entered, the fluid began to escape, and the tumor could no longer be felt. An opiate was given, and the infant slept well all night. At 6 o'clock on the following morning it began to scream, and soon thereafter passed blood and mucus from the anus. Under chloroform narcosis, laparotomy was performed, the operation occupying only eight minutes. This was succeeded by collapse, and the infant died twenty-four hours later. Necropsy was negative.

CASE XLII.—Dr. Briddon, at the meeting of the New York Surgical Society, held on the evening of May 23, 1894, *Annals of Surgery*, vol. xx., pp. 418 and 419, reported a case of intussusception occurring in an infant, aged eight months, which came under observation on the second day, in a state of collapse. Laparotomy was performed. The invagination was reduced with difficulty. Death ensued five hours later.

CASE LXIII.—Dr. J. F. Erdmann records, in the *MEDICAL RECORD*, 1895, vol. i., page 475, a case of intussusception of the enteric variety occurring during January, 1895, in a male infant, aged eight and one-half months, which came under observation on the fourth day. Enemata had previously been unsuccessfully employed. Laparotomy was performed, and the invaginated portion of the ileum, which proved to be in a gangrenous condition, was removed (six inches), and an end-to-end anastomosis effected by means of a Murphy button. Septic peritonitis existed at the time of operation, and the infant died a few hours later.

Cases of Infantile Intussusception Successfully Treated by Laparotomy.—Table No. 4. CASE I.—Mr. Marsh reported to the Royal Medical and Chirurgical Society, at its meeting held December 14, 1875 (*Lancet*, 1875, vol. ii., p. 877), a case of intussusception occurring in a male infant, aged six months, which came under observation on the first day of acute illness, giving a history of thirteen days of previous indisposition. Examination revealed an abdominal tumor, and there existed a protrusion from the anal orifice. Enemata of air and water were employed without success. A few hours later, Mr. Marsh found the infant collapsed. Laparotomy was performed, and the invaginated bowel was readily reduced. Convalescence was uneventful.

CASE II.—Dr. Henry B. Sands records, in the *New York Medical Journal* of 1877, vol. xxv., p. 561, a case of intussusception of the ileo-caecal variety occurring in a female infant, aged six months, which came under observation twelve hours after the onset. The infant was collapsed. Abdominal and rectal palpation revealed a tumor. Reduction of the invaginated bowel was first attempted by the fingers, by enemata, by the long rectal tube, by inflation, and again by enemata, and finally, as the tumor persisted in reappearing, abdominal section was resorted to. The invaginated portion of bowel was reduced with difficulty. The bowels moved two days later, and convalescence was uneventful.

CASE III.—Mr. R. J. Godlee reports, in the *Transactions of the Clinical Society of London*, vol.

xvi., p. 67, a case of intussusception of the ileo-cæcal variety, occurring during 1881, in an infant, aged nine months, which came under observation on the fourth day at which time the bowel protruded from the anal orifice. The pulse-rate was 200. Inflation with air and water was first tried, after the infant had been inverted, but proved unsuccessful. Laparotomy was performed, the invaginated portion of bowel was readily reduced, and recovery ensued.

CASE IV.—Dr. Snowball records, in the *Lancet* for November 3, 1886, a case of intussusception of the ileo-cæcal variety, occurring in an infant, aged eight months, which came under observation on the first day. Opiates and enemata having been tried unsuccessfully laparotomy was performed, and the invaginated bowel was reduced without difficulty, but the constriction was too tight to have admitted of its reduction by enema. Convalescence was uneventful.

CASE V.—Dr. Howitt, in a paper read before the American Association of Obstetricians and Gynecologists, 1894, records a case of intussusception of the ileo-cæcal variety occurring during 1888, in a male infant, aged three months, which came under observation on the second day of acute illness. Abdominal palpation revealed a tumor. Cathartics had been given, aggravating all the symptoms. Under chloroform narcosis, and with the pelvis elevated, an enema was administered. When a little more than a pint had been injected, the infant suddenly ceased breathing, and was resuscitated with difficulty. As the tumor had only been partially reduced by the enema, laparotomy was performed. The tumor was reduced with some difficulty. The cæcum and ascending colon gave evidence of having recently been involved in the invagination. Two hours later the bowels moved, and the convalescence was uneventful.

CASE VI.—The University College Hospital records, in the *British Medical Journal* for 1894, vol. i., p. 347, a case of intussusception of the ileo-cæcal variety occurring during 1889, in a female infant, aged five months, which came under observation on the second day. Abdominal palpation under chloroform narcosis revealed a tumor. Enemata were tried unsuccessfully. Laparotomy was performed, and the invagination was easily reduced. Convalescence was uneventful.

CASE VII.—Dr. Frederick Kammerer records, in the *MEDICAL RECORD* for 1890, vol. i., p. 113, a case of intussusception of the ileo-cæcal variety occurring during 1889, in an infant, aged six months, which came under observation sixty hours after the onset. The infant was narcotized with chloroform, inverted, and an enema administered under strong pressure, but without result. Laparotomy was performed, and the invaginated portion of bowel was easily reduced. Recovery resulted.

CASE VIII.—Sir William Savory and Mr. Marsh record, in the *St. Bartholomew's Hospital Reports*, 1892, vol. xxvi., p. 110, a case of intussusception occurring during 1890, in an infant, aged nine months, which came under observation on the second day. Abdominal palpation revealed a tumor. Laparotomy was performed, and the invaginated portion of gut was easily reduced. During the night following the operation, a stool was passed, which did not contain blood. Convalescence was uneventful.

CASE IX.—Mr. Paul Bush, in the *Bristol Medical-Chirurgical Journal*, 1894, p. 6, records a case of intussusception occurring in an infant, aged four months, which came under observation on the second day (May 21, 1890). Enemata had been administered without result. Under chloroform narcosis laparotomy was performed. The invagination was of the ileo-cæcal variety, and was easily reduced. The patient's recovery was uneventful.

CASE X.—MacEwen records, in the *Glasgow Medi-*

cal Journal for 1892, p. 276, a case of intussusception of the colic variety occurring during 1891, in an infant, aged nine months. When first seen it was collapsed. Laparotomy was performed, the invagination was with difficulty reduced, and in making the reduction the peritoneal coat of the gut was injured. Recovery ensued, and three months later the infant was shown in good health.

CASE XI.—Mr. Pollard records, in the *Lancet* for 1892, vol. ii., p. 880, a case of ileo-cæcal intussusception occurring in an infant, aged six months, which came under observation on the first day. Abdominal palpation revealed a tumor. Enemata repeated at intervals were given (with a head varying from two to three feet) unsuccessfully, as the tumor kept reappearing after short intervals. Laparotomy was performed, and the tumor was withdrawn. It seemed to consist only of the swollen ileo-cæcal valve, the intussusception having possibly been reduced by the enemata. Convalescence was uneventful.

CASE XII.—Mr. Barker records, in the *British Medical Journal* for 1894, vol. i., p. 345, a case of intussusception of the enteric variety, occurring during 1893, in a female infant, aged seven months, which came under observation thirty-six hours after the onset. Abdominal palpation revealed a tumor. Enemata combined with manipulation having failed to effect reduction, laparotomy was performed, and the invaginated bowel, although strangulated, was easily reduced by pressure from below. Recovery followed the operation.

CASE XIII.—Mr. Verrall records, in the *British Medical Journal*, 1893, vol. ii., p. 1,375, a case of intussusception of the ileo-cæcal variety occurring during 1894, in a male infant, aged six months, which came under observation on the first day of the acute attack. Abdominal palpation revealed a tumor. Under anaesthesia an enema of eight ounces of water was administered, the elevation of the reservoir being two feet. This procedure had no effect on the tumor. Laparotomy was performed, and the invagination was reduced with difficulty. The bowels moved naturally the succeeding day, and the infant recovered.

CASE XIV.—Dr. Beatley and Mr. Ridley record, in the *British Medical Journal* of 1894, vol. i., p. 911, a case of intussusception of the ileo-cæcal variety occurring during 1893, in an infant, aged eleven months. When it first came under observation, it was stated that the infant's bowels had been deranged for eleven days. Abdominal palpation revealed a tumor. Under chloroform narcosis enemata had been given at frequent intervals, but without result, and many hours of valuable time were thus lost. Laparotomy was performed. The tumor was reached with difficulty owing to the intestinal distention, but was easily reduced. Before the intestines could be returned within the abdominal cavity they had to be incised to allow the gas to escape. The bowels moved on the second day after the operation. The convalescence was retarded by the occurrence of a persistent diarrhoea.

CASE XV.—Mr. Lockwood records, in the *Lancet* for June 3, 1893, a case of intussusception occurring in a male infant, aged eight months, which came under observation twenty-eight hours after the onset. Enemata were unsuccessfully tried under chloroform narcosis. The first consisted of ten ounces of water with a head of two and one-half feet, and the second of twelve ounces with a head of three feet. Laparotomy was performed. The time required for the administration of the enemata and the performance of the laparotomy was thirty-five minutes.

CASE XVI.—Mr. A. E. J. Barker reports, in the *British Medical Journal* of 1894, vol. ii., p. 1,237, a case of intussusception occurring in a male infant, aged four months, which came under observation during

1894, on the second day. Abdominal palpation revealed a tumor. The infant's general condition being bad, enemata were omitted. Laparotomy was performed and the invaginated bowel pressed out of the intussusciens. This manipulation injured the peritoneal coat in several places. The cæcum was darkly congested, swollen, and devoid of polish. The operation was followed by little shock, and the bowels moved several times during the night, each movement containing less blood. Convalescence was uneventful.

CASE XVII.—Dr. Ainsley records, in the *Lancet* for 1894, vol. ii., p. 1,247, a case of ileo-cæcal intussusception occurring in a male infant, aged eight months, which came under observation on the first day. When seen, the infant was collapsed. Abdominal and rectal palpation revealed a tumor. Inflation was unsuccessfully tried under chloroform narcosis. Six and one-half hours after the onset laparotomy was performed, and the invagination reduced. The time required for the operation was forty minutes.

Commenting on this case, Dr. Ainsley said: "The difficulty in unravelling the bowel, as well as its congested and œdematous condition, makes us believe that had the operation been postponed even for a few hours the chances of success would have been very seriously jeopardized. I am also persuaded that prolonged inflation or injection of water could have done nothing but harm."

CASE XVIII.—Mr. Pollard records, in the *Lancet* for 1894, vol. i., p. 473, a case of intussusception of the ileo-cæcal variety occurring in a female infant, aged seven months, which came under observation on the first day. Rectal and abdominal palpation revealed a tumor. The dejections had a gangrenous odor. Laparotomy was at once performed. The invaginated bowel was reduced with some difficulty, the infant's bowels acted naturally twenty hours later, and convalescence was uneventful.

CASE XIX.—Mr. A. E. J. Barker records, in the *British Medical Journal* for 1894, vol. i., p. 345, a case of intussusception occurring in a male infant, aged five months, which came under observation during 1894. Enemata were administered with apparent success, as the tumor disappeared, but it soon returned. Laparotomy was performed, and the invagination was reduced. Recovery followed the operation.

CASE XX.—Dr. Roberts records, in the *Philadelphia Medical and Surgical Reporter* of 1894, p. 428, a case of intussusception of the ileo-cæcal variety, occurring in an infant, aged nine months, which came under observation on the fourth day. Enemata were first tried. Then laparotomy was performed, and the invagination was easily reduced. The time occupied by the operation was twenty-five minutes. The infant's convalescence was uneventful.

CASE XXI.—Dr. Howitt, in a paper read before the American Association of Obstetricians and Gynecologists, 1894, records a case of intussusception of the ileo-cæcal variety occurring in a male infant, aged six months, which came under observation on the second day. Cathartics and enemata had previously been unsuccessfully employed, as was Senn's plan of rectal insufflation with hydrogæa gas. The infant's condition was bad. Laparotomy was performed, and the invaginated gut was difficult of reduction. The infant's bowels moved the same evening, and its convalescence was uneventful.

Remarks.—The total number of cases of infantile intussusception collected and reported in this paper is 103. Of these nearly 50 per cent. occurred during the fourth, fifth, and six months, in nearly equal proportions; 75.4 per cent. of the cases occurred in males, and 89 per cent. were of the ileo-cæcal variety. Pritchard in his paper on intussusception called attention to the probable part played by external violence

in the causation of this disorder during early life, particularly the careless manner in which infants are picked up and doubled over the arm of those caring for them, thereby injuring and causing a temporary paralysis of some portion of the intestinal canal. Jacobi has also called attention to this matter, particularly to the way in which infants are violently jumped up and down to quiet their cry. This seems to have been the prime factor in the causation of the invagination in the writer's case. The age during which the infant is most liable to be affected by this disorder seems to substantiate these views. In one case the invagination was caused by an intestinal tumor.

In these cases there seems to be nothing of unusual interest in the symptomatology to record. The disorder manifests itself by means of a sudden onset of severe abdominal pain, followed by vomiting and the passage of stools containing blood and mucus. Tenesmus was present to a marked degree only in those cases where the gut protruded from the anal orifice, or where the tumor was down in the rectum. The symptoms varied in intensity in the usual manner, in direct proportion to the degree of constriction the bowel was subjected to, as indicated by the character of the pain and the amount of blood passed from the anus. The sign of the disorder, an abdominal tumor, was seldom absent, as was to be expected in such a large proportion of cases of the ileo-cæcal variety. Several of the reporters call attention to the necessity in all suspected cases of this trouble of making a conjoined abdominal and rectal examination, for in some instances a tumor was revealed by this means after abdominal or rectal palpation alone had failed to discover it.

A protruding anal tumor occurred in the usual proportion—about six per cent. of the cases.

Cure by sloughing, which is exceedingly rare in these cases, was met with twice, in Beeston's case and in one recorded by Mr. Cripps in the St. Bartholomew's Hospital Reports for 1892, of which a few particulars will here be given, it not being included in the collection.

The case occurred during 1882, in a female, aged three months, which came under observation on the fourteenth day, with a gangrenous mass of gut protruding from the anus, a portion of which was removed. The rest sloughed off, and the patient recovered.

Thirty-nine of the cases were treated only by means of inflation, or enemata, or both. Of these, sixteen, or forty-one per cent., recovered. The average hour after the onset when the treatment began was the forty-first. The histories of these cases are so deficient as to the details of the quantity of fluid or the amount of pressure employed that no deductions can be drawn in regard to these points from this group. In two cases, eight ounces of water were used; in two cases, one pint; in two cases, one quart with a head of from three to four feet; and in one case, three quarts under a head of five feet was reported as having been the amount injected into the intestinal canal of an infant seven and one-half months of age. In one case, nine enemata were required to bring about a permanent reduction of the invagination, as evidenced by the disappearance of the tumor and the subsidence of the symptoms. Chloroform narcosis was employed in three cases while the distention of the bowel was being effected.

The cases of this group which terminated fatally were twenty-three in number, a mortality of fifty-nine per cent. The average age of the infants was about five months. The average hour following the onset when treatment was begun was the sixty-ninth. In one case while the enema was being administered under chloroform narcosis, and in the inverted position, the infant vomited, inspired the vomited material, and died. In several cases, collapse followed the admin-

istration of the enema, and in nearly all cases there is the same story of the inefficiency and uncertainty of the method, the tumor disappearing only to return after a short interval, and the treatment repeated again and again, the occasional repeated administration of chloroform with alternating injections of air or water combined with massage, often roughly applied, till finally death mercifully came to the infant's relief. In all of these cases where notes of a necropsy were found, the same tale was told of gangrenous, unreduced, invaginated bowel; invaginated bowel easily reduced by internal manipulation or traction; or bowel lacerated as a result of the violence caused by the over-distention of the diseased intestine. In one instance, the gut was found to have become gangrenous twenty-eight hours after the first onset.

If all the cases are counted in which intestinal distention was practised to reduce the invaginated bowel, some of which cases were afterwards treated by abdominal section, we will find that their number is 72. Of this number, failure to effect reduction occurred in 54 instances, or 75 per cent., which percentage would have represented the mortality of this method of treatment had not other means been afterward tried, taking them out of this category. These figures approximate closely to those given by Hare as the percentage of mortality following this method of treatment. In one instance where laparotomy was performed after enemata had apparently failed to effect a reduction, as evidenced by a continuance of the symptoms, it was thought that the swollen ileo-cæcal valve had, after the reduction of the invaginated bowel, simulated the tumor; and in another case it was supposed that the invagination had been reduced by the distention but that the bowel had become paralyzed and had been unable to recover itself.

While the experiments of Forrest, Curtiss, and others prove that there is little or no danger of injuring healthy infantile intestine by a hydrostatic pressure of six pounds to the square inch, the experiments of Mortimer and Mole and the practical experience set forth in this paper demonstrate conclusively that the conditions are very much altered when we have to do with a portion of gut that has been severely constricted, even for a few hours. Battey and Mole have proved by their experiments that water under a moderate pressure can, when no obstructions exist, be made to pass through the ileo-cæcal valve, and Mole has proved that one and one-half pints of water injected under a pressure of one and one-third pounds to the square inch, into an infantile colon, will fully distend it, and that it will pass the valve. Therefore, it would appear that if it is desired to treat a case of infantile intussusception by means of intestinal distention (which the writer freely admits, after a careful study of this subject, notwithstanding the fact that the only case which has come under his personal observation was successfully treated by enemata, he would be unwilling to employ) at least one and one-half pints of tepid saline solution (one teaspoonful of salt to the quart) should be placed in a reservoir which is not to be elevated above three feet; and if this is not successful after one trial the method should be abandoned, and other means to effect a reduction employed. If it is thought that reduction has occurred under this method, as evidenced by the apparent disappearance of the tumor, the infant should be placed in its crib and quieted by other means than by opiates or motion, to the end that if reduction has not really been effected the fact may be made manifest by the symptoms at the earliest possible moment, so that other treatment may be attempted while the chances of a successful outcome, though diminished, are not absolutely gone. It is well to recall the fact that in those cases which were successfully treated by enemata the average hour after

the onset at which treatment was begun was the forty-first, and in those cases which terminated fatally it was the sixty-ninth.

Mr. Mortimer, in the course of a paper entitled, "On the Treatment of Intussusception by Injection or Inflation, and its Dangers," *Lancet*, 1891, vol. i., p. 1,144, said: "That in his opinion the chief advantage of this method of treatment lay in the slight parental opposition to its employment." In alluding to the objections of this method, he said: "A serious objection to the operation (enema) is that the conditions under which it is performed can only be roughly guessed at. An invagination of a fairly healthy intestine may at one time remain unreduced, when a little more pressure would have completely unfolded it, while at another time a very slight force may be enough to cause rupture. There is always afterwards a deceptive lull of some hours, due to effects of shock, to the anæsthetic, cessation of feeding, as well as to the opium which is usually given. Such delay may so alter the general and local conditions as to render hopeless any further procedure. It is also true that an experienced operator may blindly do as much damage as the merest tyro. I need not dwell on the obvious value of being able to feel and see what one has to deal with, both as regards the intussusception and the various complications which may accompany it. There is seldom hesitation in performing an operation, perhaps a serious one, in the most unfavorable cases, say of ruptured aneurism or obstructed labor, or in ascribing a fatal ending less to the operation than to the condition which necessitated it. To this class acute intussusception in the late stage belongs."

In the course of the discussion which followed the report of Mr. Mortimer's case of intussusception unsuccessfully treated by enemata, Mr. Bryant said: "In my opinion under all circumstances the treatment by intestinal distention is dangerous, although successful cases may be occasionally recorded, and it is only justifiable within the first three days, and in cases not presenting symptoms of acute strangulation." The speaker also considered manipulations through the abdominal wall during the administration of enemata as being dangerous.

Mr. Pritchard, in the course of his paper entitled, "Intussusception," *Bristol Medico-Chirurgical Journal*, 1894, p. 7, said: "I think a child would stand a far better chance of getting well after an abdominal section and the disentangling of the invagination by the fingers than by the influx of water, if the irrigator had to be elevated higher than three feet to bring about a reduction;" and finally Dr. Charles K. Bridson, surgeon to the Presbyterian Hospital, in a recent communication to the writer, said: "From what I have seen of the cases brought into hospital *in extremis* and the great difficulty of reducing the parts at that time, I should judge the use of intestinal enemata as simply trifling with a very grave condition, only to be combated by the institution of radical measures at the outset."

The history of the treatment of infantile intussusception by the method of intestinal distention, by either air or water, as evidenced by the testimony which has been presented, is certainly a dark page in that of our science. It is a story of empirical, rather than scientific, endeavor, one of hope deferred, of uncertainty, of prolonged torture, none the less cruel because it was performed in all kindness, and was generally considered to be the gentlest method of dealing with the disorder, and finally of a mortality of seventy-five per cent. of disaster.

Laparotomy was performed in this group of cases 64 times for the relief of infantile intussusception. It resulted successfully in 21, or in 32.8 per cent. of the cases operated upon. The average age of these in-

infants was about six and one-half months. The average hour from the onset till the time of operation was the forty-fourth. In 17 of the cases inflation and enemata, or both, had previously been tried without success. In 8 cases the invaginated bowel was readily reduced, and in 10 cases it was reduced with difficulty. In 3 of the histories nothing was stated regarding this point. The length of time required for the performance of the operation was in one instance stated to be eight minutes, and in another thirty-five minutes, which latter included the administration of an enema.

Laparotomy was followed by death in 43 of the cases, giving a mortality of 67.2 per cent. The average age of these patients was about five months, the youngest upon whom enterectomy was performed being only three days old. It lived six days thereafter, probably dying of inanition, as the operator opened the first piece of bowel which presented itself in the wound. Had he sought for and reduced the invaginated bowel, it seems almost certain that the infant would have recovered. If these cases are subtracted from our list of unsuccessful abdominal sections in which either the operation was abandoned, the bowel incised and an artificial anus made or resected, and an anastomosis effected, we shall have 45 cases, of which number only 24 resulted fatally, reducing the mortality to 53.4 per cent.

If we count only the operations, successful and unsuccessful, that have been performed since the perfected technique of abdominal surgery has become generally known—say, since 1889—and throwing out as before the cases in which the operation has not been completed, the bowel incised or excised, we have a total of 18 cases, of which 14 were successful, and 4 were unsuccessful, giving a still lower percentage of mortality, or 22.2 per cent., which the writer believes is a fair estimate of the risk to-day of abdominal section performed on a young infant for the relief of this disorder, if performed within the first forty-eight hours of the onset.

It would seem that if an infant suffering from this disorder were first seen in collapse, it would be wise before attempting the operation to stimulate the infant, and if it responded, to proceed; otherwise it would be useless to do so. The operators in these cases have almost invariably employed the median incision satisfactorily. The best method for reducing the invaginated portion of bowel seems to be that wherein the tumor is encircled below its apex by the finger and thumb, while the intussusciens or sheath is held a few inches lower down, the apex of the tumor being pushed in an upward direction. Traction from above the tumor should not be employed. If, however, the tumor prove irreducible (although so far as the writer has knowledge there is no recorded case of intestinal resection or an artificial anus in an infant under twelve months of age which has proved successful), it is the writer's belief that the method devised by the late Prof. H. Widenham Maunsell, which is shown in Fig. 1, is the best that has been devised for treating this most unfortunate complication, caused by delay.

A slit is made in the intussusciens and gentle traction made on the intussusceptum until its neck appears outside the opening in the intussusciens. The base is then transfixed with two straight needles armed with horsehair, and the intussusceptum is amputated a quarter of an inch above the needles, leaving a fair stump beyond them. The sutures are now passed through the invaginated bowel, caught up in the interior of the bowel, divided and tied. This having been accomplished, the invagination is reduced, and the longitudinal slit is closed.

Disastrous as we have already proved the treatment of infantile intussusception by means of intestinal distention to be, the results obtained from 1828 to 1889,

when abdominal section was finally resorted to, seem to have been even more so, giving as it did a higher percentage of mortality, or 84 per cent., as against 75.4 per cent. But it must be borne in mind that it was always a last resort, only employed after the little patient had become collapsed by days of severe pain, inability to take and retain food, persistent, often hourly, torture by inversion, the administration of anaesthetics, enemata of air and water, massage, to which not unfrequently was added the so-called long rectal tube. Nothing more surely could be devised to unfit an infant or adult to withstand the nervous shock which must necessarily accompany the administration of an anaesthetic, the opening of the peritoneal cavity, and the manipulation of the intestines. As one case of section proved unsuccessful, and its result was reported, it almost certainly added danger to the next case that came under the surgeon's care. In an editorial comment in a number of the *Lancet* for 1891, on a case of intussusception treated by enemata, which resulted

FIG. 1.—Diagram of longitudinal section of intestine, showing an acute irreducible intussusception, and the method of its treatment. C C, longitudinal opening made in the superior border of the intussusciens; A A, apex of intussusceptum; B B, neck of the intussusceptum.

fatally, it was said: "It is true that the invagination can always be reduced, at all events in the early stages of the disease, by the operation of laparotomy, but this operation is attended by such a large percentage of mortality when undertaken in infants that the surgeon shrinks from performing it until all other means have been tried and failed." Mr. Lawson Knaggs, in the course of his able article entitled, "Resection for Gangrenous and Irreducible Intussusception," *Lancet* for 1887, vol. i., p. 1,179, said: "This waiting policy, this surgery of hope, has so far been a dismal failure, nor should we forget that in all cases that last chance is far too poor to be relied upon for permanent success, and that in infants it practically does not exist."

Rydygier, of Cracow, in discussing intestinal invagination at the last meeting of the German Surgical Congress, held in Berlin during April, 1895, is reported to have said: "The cases are usually treated too long by internal remedies, and accordingly come too late to the surgeon. The mortality is, therefore, very high, seventy-five per cent., especially in acute cases."

Further testimony or argument would seem to be unnecessary, and we must at least begin to realize the important part played by delay in these cases, as it has in all other forms of intra-abdominal disease, in affecting the prognosis unfavorably.

If by this clinical demonstration of the disease, and of the results of its treatment from 1828 to 1895, the

general profession and the laity could be impressed with the facts that acute intussusception is in reality a form of strangulated hernia; that the subacute variety is an irreducible hernia; that enemata are far from being devoid of danger in their administration; that abdominal section performed under modern conditions and during the first forty-eight hours of the disorder, has a chance of success represented by seventy-eight per cent., which would speedily rise to ninety per cent. as the cases came more frequently under operation during the first twenty-four hours, it would not be long before we should come to look upon the treatment of this disease by enemata of air and water much as we do to-day upon the pukes, purges, doses of metallic mercury, of gold and silver balls, of mixtures of bird-shot and olive oil, and blood-letting which were soberly employed by good men not so many years ago for the relief of this distressing disorder, made more painful by reason of the heroic treatment considered necessary for its relief.

With the light turned fully on what modern surgery has already accomplished in this direction, it is a safe prediction that before the dawn of the twentieth century it will be generally acknowledged that our science has fully and finally triumphed over another of her malignant foes, infantile intussusception.

35 WEST THIRTY-SIXTH STREET.

BICARBONATE OF SODA IN THE TREATMENT OF A "COMMON COLD."

BY L. DUNCAN BULKLEY, A.M., M.D.,

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

HAVING very recently again broken up what threatened to be a very severe "cold" in myself by the method of treatment to be described, I wish to present the matter briefly to the profession, even at the risk of writing on a subject with which all are supposed to be familiar. I may add that I have practised this method for something over two years, both professionally among my patients and casually in my family and among my friends and acquaintances, and am well satisfied of its value.

The observation as to the control of bicarbonate of soda over a "common cold" came to me quite accidentally. I had experienced the general symptoms of shivering, coryza, sneezing, etc., and expected its full development as usual, as I had always been, perhaps more than is common, subject to "colds."

Happening to have a little stomach acidity, I took a fair dose of bicarbonate of soda in some water. Half an hour later, as there was still some acidity, I repeated the dose of soda, which gave the required relief to the unpleasant stomach symptoms. About an hour later I noticed that I felt less of the symptoms of the "cold," and the thought occurred that possibly the repeated doses of soda had something to do with it.

Recognizing that all individuals are not equally "subject to colds," and also that the same individual may exhibit a stronger tendency thereto at one time than at another, I have long felt that the susceptibility to this affection depended upon some state or condition of the system, commonly present or occasionally developed. Observation had also long convinced me that while it is not persons with a marked gouty diathesis, or in an active gouty state, that are mainly subject to "colds," these latter are more frequently seen in those exhibiting minor forms of acidity, and in those in whom it has quickly developed from some cause or other.

It therefore occurred to me at once that the slight relief to my "cold" had been indeed from the soda, neutralizing the acidity which had developed from the

deranged stomach action. I therefore took another good amount of the remedy about an hour from the last dose, and, finding that the symptoms of "cold" were steadily lessening, I took still another full dose, about an hour later (as far as I can remember, for this was two years and more ago), and thought no more of the "cold," as it had passed away.

Some time after, having again a "cold" which was troublesome, I remembered my former experience, and took the soda repeatedly, with the same effect. I then used it a number of times in members of my family, always with advantage, and since that time have recommended it to patients and friends with increasing confidence.

It is important, I think, that the soda should be taken just rightly, and a definite plan carried out thoroughly; for I have never seen any effective results from a desultory use of the remedy.

After many trials I have settled down to the following plan for an adult of medium size and weight. Twenty to thirty grains of the bicarbonate are given in two or three ounces of water, every half-hour, for three doses, and a fourth dose at the expiration of an hour from the last one. Two to four hours are then allowed to elapse, to see the effect, and the four doses are repeated if there seems to be necessity, as is frequently the case. After waiting two to four hours more, the same course may be taken again, although this is not often necessary, if the treatment has been begun early in the course of the "cold." I have known the doses to be repeated four times, with final good result.

As intimated, the method of treatment under consideration relates more especially to the early stage of a "cold." To be promptly effective, it should be begun with the earliest indications of coryza and sneezing, and in my experience has rarely failed to break it up, even in those much inclined to the same. After the second or third day it acts less promptly, and more frequent repetitions are needed, but I have seen very good results even much later in the trouble.

When the influenza has more of the contagious character, now recognized as "grippe," it is less efficacious, but is still often of service. In these cases I have combined phenacetin, five to ten grains, with ten to twenty of soda, and given the powders, with hot water, every two hours continuously for a day or two. I have had a large number of very striking instances of the benefit of this plan of treatment, both in the past two years and during this fall and winter; in some cases the treatment has been begun several days after the commencement of the disease, and in one instance after it had lasted about four weeks. The latter case occurred quite recently, and the almost immediate relief to many distressing symptoms—headache, cough, malaise, etc.—was very striking. The patient was a remarkably intelligent gentleman, aged forty-five, who had been under varied treatment for the entire time.

I have little to add in regard to the *modus operandi* of the treatment. It is based, as already stated, upon the idea that there is an acid condition of the system developed, which is sufficient to irritate the terminal endings of the nerves in the skin and mucous membranes, and so to render them susceptible to impressions of cold, by a derangement of the capillary circulation. As this acidity is neutralized, the normal conditions return. All are familiar with the favorable effects of diaphoretics, whether medicinal or mechanical, as in the case of hot-air baths, or hygienic, as in frictions and exercise, in breaking up a "cold." The soda seems to act in relieving the internal cause of the surface irritation, and has always been used singly and alone, without the aid of other measures.

In regard to the dosage, twenty to thirty grains, so

often repeated, I may say that I have never seen cause to regret the employment of this method, and have never known any later ill effects therefrom. The dose of bicarbonate of soda is stated to be from ten to sixty grains, while some of the other preparations of soda may be taken in very much larger quantities—notably the sulphate of soda, often given in from one-half to one-ounce doses.

In presenting this brief mention of a plan of treatment which has become a very common one with me, I trust that it may be given a careful and fair trial by the profession; if faithfully used as directed, I feel confident that it will often be found serviceable, not only in giving relief to what is frequently a very annoying trouble, but also in averting later complications which may follow in the wake of a "common cold."

CONGENITAL DOUBLE FISTULA OF THE LOWER LIP SIMULATING A SUPERNUMERARY NOSE.

BY LEWIS H. MILLER, M.D.,

BROOKLYN, N. Y.

CONGENITAL fistula of the lower lip is one of the most rare as well as the most curious of physical defects even when found in infantile life, but in this instance of congenital double fistula of the lower lip so markedly resembling a supernumerary nose in an adult patient one would seem to have a unique case.

Even in infantile life we are able to find on record only three cases of congenital fistulæ of the lower lip and only one of those was double and could claim any marked resemblance to this case.

Demarquay was the first to notice and describe a case of single congenital fistula, close to the middle of the lower lip.

Next, I quote from Keiting's "Cyclopedia of the Diseases of Children," "Fritche has reported an extraordinary instance in the case of a female infant of five months. He found an opening on the margin of the lower lip; from this a sinus ran downward and inward in the thickness of the lip and cheek and terminated underneath the mucous membrane, which appeared to be lined with mucous membrane and which when the child cried appeared to open and discharge some drops of fluid. A communication with the mouth could not be found."

The third case, which, had the child lived to years of maturity, might have more closely resembled my own case, is thus described: I again quote from Keiting:

"In a case reported by Rose were seen two symmetrical fossæ which led down into fistulæ whose passage terminated by a blind extremity, about three centimetres from their opening. The two fistulæ ran in the thickness of the lip somewhat nearer the mucous membrane than the skin. In this case there were other congenital defects, including a well-marked fissure of the upper lip."

My patient is a young lady, seventeen years of age, of German parentage, and aside from the condition in question has a cleft of the soft palate involving two-thirds of that organ, with a uvula, or one-half of a uvula, on either side. Otherwise she appears healthy and well developed. When her mouth was closed, from a habit she had contracted of holding the under lip in with the upper incisor teeth, none of the deformity appeared, but as soon as the lips were opened, there was presented in front of the lower incisors what looked like two nostrils, as though a nose by some plastic operation had been placed on the inner side of the lower lip.

These openings which appeared like nostrils extended down into the thickness of the lip over two centimetres. As in Rose's case they were lined with mucous membrane, but unlike his terminated in separate cul-de-sacs and were very widely separated, there being a raphe between them on the inner side of the lip. And instead of a doubled fissured upper lip, resembling a well-known form of hare lip, in this case there was a partial cleft of the soft palate.

To remove this deformity of the lower lip, after anæsthetizing with ether, I simply took out a V-shaped piece from the inner wall of each fistula, dissected out the lining membrane, and stitched down the flaps thus formed.

Aside from the rareness of this condition of the lower lip and the wonder that in this case such a deformity should have been left undisturbed till adult life, as Keiting suggests, the nature of these fistulæ is very hard to explain; they are lined with membrane, although it is not generally known that they secrete any fluid.

By themselves he says they constitute a defect of slight importance, a statement which he would not have made had he seen this case; but, as he adds, they are of extreme interest from an embryological point of view. It would seem to be a significant fact, however, that two out of the four cases reported presented elsewhere some mark of imperfect development: the one on the upper lip and the other on the soft palate. Yet there is no condition of embryonic life with which I am acquainted whereby this could be considered a result of imperfect development.

If any one can enlighten me on the etiology of congenital fistulæ of the lower lip I should be pleased to hear from him.

Clinical Department.

SUSPENSION IN THE RESUSCITATION OF THE NEW-BORN.

BY MARK I. KNAPP, M.D.,

NEW YORK.

On the morning of December 18th I was called next door to complete the second stage of labor in a case attended by a midwife. The cause of my having been summoned was that the child's head had been out of the vagina for about thirty-five minutes, while the rest of the body had remained unborn. The head of the child, which was markedly cyanotic, was facing the mother's right thigh. Searching for the cause of the arrested progress of the labor, I found a coil of the umbilical cord surrounding the child's neck. Time was precious. So instead of any other manipulation I at once endeavored to secure the liberation of the child, tied the cord and then cut it. An attempt to extract the child by its head proved futile, so my next step was to free the lower arm, which I succeeded in doing by helping it along with my left index and middle fingers in the rectum of the mother. This arm out, the rest of the child followed quickly. But unfortunately, as I expected, the child made no attempt either to breathe or to cry. A hasty auscultation, probably faulty, revealed no heart beat. I do not remember to have felt for pulsation in the cord in that excitement. Now, what method of resuscitation? The alternate use of hot and cold water suggested itself to me first, and after a trial of about two minutes' duration my efforts were awarded by a shallow gasp. I discarded this as too tiresome. An attempt at Sylvester's method did not promise to be effectual. Suspension by the feet, as reported by Dr. Bissel in the

MEDICAL RECORD of November 30th last, I thought to be in place here, and wrapping the child in warmed flannel sheets I had the father hold it by the legs, head down. The expected result began at once to manifest itself. A few gasps were followed by irregular breathing first, then regular, interrupted at every ninth or tenth breath by an attempt to cry, which sound was short, abrupt, flapping, and of a somewhat sighing nature. With the regular breathing the color of the child changed gradually to normal. I several times introduced my fingers into the child's mouth with the view of clearing it, and once I felt the child suckle at it, and on withdrawing my finger it attempted to cry. Thinking now that my finger irritated the child into crying I repeated my experiments, with good results. I kept the child suspended for about forty or fifty minutes, and whether necessary or not I extended and then flexed the head upon the sternum at the beginning of the suspension. The child, after it once began to cry lustily, was placed at the mother's side and it has remained well.

I should like to call attention to the irritation of the pharynx, which proved to be useful in my case, as causing the child to cry.

Whether the gravitation of the blood to the head alone, or, in addition, the mechanical pressure of the abdominal viscera upon the diaphragm and the phrenic nerves, is to be held responsible for stimulating respiration is a matter of speculation.

141 SUFFOLK STREET.

A MONSTROSITY.

By WM. A. B. TREADWAY, M.D.,

STAMFORD, CONN.

To the list of monstrosities reported by Dr. Boweman, of Ontario, and Drs. Hinman and Wood, of Michigan, I present a case in which the liver and intestines protruded through a ventral opening.

There was a denudation of the dorsal and cervical spines and base of the brain, a remarkably short cord, and an enormous quantity of liquor amnii from the uterus which contained the monstrosity. The mother had given birth to five healthy and well-formed children, four of whom are alive now. There was no family diathesis that could be learned.

The writer having been called to relieve the patient from pain on account of a greatly distended abdomen, found, upon examination, a slightly dilated but rigid os. The patient said that she was in her last month of gestation. Palpation failed to outline the position of the uterine contents, and on auscultation I was unable to detect the fetal heart sounds. Hypodermic injections of morphine relieved the woman's distress during the night, and in the morning the protruding membranes were ruptured by the finger, when the liberated liquor amnii more than filled a large-sized water-pail at the side of the bed. Immediately after the rupture of the membranes the head descended, the face presenting, and delivery took place. The placenta was of normal size and appearance.

WHEREIN ANTITOXIN PROVED A VALUABLE DIAGNOSTIC MEANS.

By J. D. HERRMANN, M.D.,

EASTMAN, GA.

On November 15, 1895, at 5 P.M., I was hurriedly called to see a child one year old, to remove a foreign substance from the wind-pipe. Upon arrival I obtained the following history:

On the day previous, while at dinner, the child be-

came suddenly choked, the mother stating she had removed with her finger a small piece of the breastbone of a chicken but was satisfied that a small portion still remained and was lodged in the windpipe. The child's dyspnoea and appearance seemed to bear out the history. Upon examination of the throat I found that both halves of the tonsils and uvula had a decided diphtheritic appearance. This, of course, aroused my suspicion, but I was still doubtful of the diagnosis, for, as the mother had tried repeatedly to remove the bone, it was possible that she had injured the soft parts.

The child had suppression of urine, and a microscope not being available, I was prevented from arriving at a diagnosis. The child was put under the usual treatment for diphtheria until the next morning, awaiting developments. In the mean while the dyspnoea increased to such an alarming extent that tracheotomy was almost decided upon.

Being yet undecided as to the foreign substance, at 11 P.M. three cubic centimetres of antitoxin was injected between the shoulders. At 6 P.M. of the same day the condition remained unchanged, influenced only by the action of the antitoxin. At 7 A.M. the following day the child's dyspnoea was much improved and the membrane was disappearing rapidly. At 6 P.M. the child's breathing was almost normal and the membrane had almost completely gone. The patient was kept up on whiskey and strychnine and other supportive treatment during her entire sickness, and she made an uninterrupted recovery.

To-day I saw the child, one month from the day I was first called, and found her perfectly well, with no indications of any foreign substance in the windpipe.

The point of interest in the case is that, had it not been for the administration of antitoxin, tracheotomy might have been performed, without benefit and very probably with disastrous results.

A CASE OF CANCRUM ORIS FOLLOWING CAPILLARY BRONCHITIS—DEATH.

By WALTER B. WINE, M.D.,

STANFORD, MONT.

A. S.—, white, male, aged nine months, family history good, previous history excellent, came under my care December 30, 1894, suffering from capillary bronchitis. The usual treatment was prescribed. Recovery was uneventful, and the case was dismissed on January 5, 1895.

February 5th.—I was again called and found the following: Respiration and pulse rapid, temperature $103\frac{1}{2}^{\circ}$ F.; there was slight diarrhoea; the child was fretful and refused to nurse; its lower lip was slightly swollen, everted, and fissured near the median line; the breath was fetid.

February 6th.—Temperature is slightly increased. There is an ulcerated spot of the gums in left lower molar region; necrosis of the maxilla is also beginning at this point and emits a very fetid odor.

February 7th.—Symptoms graver, lower lip slightly everted, presenting a circumscribed gangrenous area about size of a dime, which is dry, indurated, and cold.

February 8th.—Temperature 104° F., respiration and pulse very rapid; nearly the whole of the lower lip is now gangrenous, involving also the lower part of the left cheek.

No attempt was made at cauterizing the necrotic tissues, as some authors recommend, and the case terminated fatally. This case is reported here because of its infrequent occurrence.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 18, 1896.

THE EVOLUTION OF THE DOCTOR.

ONE can hardly fail to believe that the contemporary English physician is a very superior kind of a man, for he is nowadays getting so many pleasant things said about him. We recently quoted a eulogy on the doctor by the well-known author, Ian Maclaren. Now from another source come statements equally gratifying to the self-esteem of the physician. The Rev. August Jessop, of Norfolk, says in the *Nineteenth Century*:

"It is becoming plainer and plainer to some of us that of all the learned professions the medical profession has of late years risen higher than any other in the public estimation, and that the *status* of the medical man is tending to become recognized as entitled to precedence above that of any other class in the community. For myself, I incline to believe that this is inevitable."

This is the kind of sentiment which we ourselves have expressed, and in which we believe. The doctor of to-day, who has passed through the educational work which makes him a thoroughly competent physician, has gained thereby a knowledge which cannot fail to make him a man of value in any community and of importance in all communities which are civilized and intelligent. At the present day the medical man can rarely succeed unless he has merit. In olden times it was largely a question of bearing and a wise look, peculiarities of dress, fashion, and manner, which took the people. Now it is expected that he show knowledge and skill, or else acknowledge that the problem is too great for him. "The average doctor stands before his fellows as a plain embodiment of the mastership of truth and knowledge on the one hand, and perfect simplicity of character and conduct, on the other." The *Hospital*, from which we quote this last, adds, however, a fear lest the bright prospects of the future be marred by the now increasing taint of commercialism. It says that doctors are becoming too fond of money, and are too much inclined to advertise and place their work upon a basis of trade. This is the kind of fear which has been expressed for many years, and which we have never seriously shared. There is something in the character of the work done by the physician which will always make his calling a distinct one, tinged perhaps with commercial methods, but not genuinely identi-

fied with such pursuits. As long as the physician is competent and honest, we do not fear that his desire for money will lower his professional standing. The greatest artists in music, in painting, in architecture have never denied themselves the sweet solace of large fees for their work. The most successful financiers or statesmen have not been thought the less great because they won large sums of money, or because pecuniary gain was one of the main objects of their life.

SCIENTIFIC COOKERY.

WE are inclined to think the medical profession owes something to the city of Philadelphia, on account of its producing a particularly enlightened and progressive student of the noble art of cookery in the person of Mrs. Rorer. This lady has published cook-books which, we are informed, are trustworthy, and has contributed to periodicals, teaching those housewives and cooks who are humble enough to be willing to learn the sane and rational methods of cooking and presenting food. Mrs. Rorer also has time to lecture and instruct in the different cities of this country, and, while we are not quite sure that all the lady says will be accepted by sanitarians and professional hygienists, yet she undoubtedly throws off some sparks of wisdom which ought to illumine wide areas in this dyspeptic country. Potatoes, as we understand Mrs. Rorer, are little better than poison if eaten in any excess. One potato a day seems to be the Rorer limit. Medical experience, in a measure, confirms the fact that the potato is not the best type of vegetable for brain workers—at least, for the neurotic type of individual—though it does well enough for those who work outdoors all day. To eat pickles is to show a lack of education, according to the Rorer gospel. To eat them in this country rather shows that the person is in a stage of adolescence, or is suffering from certain hysterical tendencies. Pickles and candy seem to be the two things to which the nervous activity of maturing young people naturally tend. To eat them shows rather a lack of balance than of training. Cooked apples are more easily digested, but not so good for the health, says the lady. The sugar in fruit is digestible, but the sugar of commerce is an abomination. Oatmeal is a valuable food if cooked for three hours and well masticated, and all starchy foods must be cooked for hours. These are truths which medical experience abundantly corroborates. Dr. McCall Anderson, for example, states that oatmeal, which causes eruptions and pruritus in some people, can be eaten without any unpleasant results if it is cooked for three or four hours. Cabbage and onions meet approval, provided they are cooked so that they have no odor. When there is odor they are ruined for food. And the art of cooking them without odor consists in keeping them in water that is just below the boiling-point. Mrs. Rorer seems to think that Welsh rarebits are better and more digestible than bread and butter, and she herself eats one every day for lunch.

The art of medicine is closely allied to that of

dietetics and cooking, and we make no apologies for calling the attention of our readers to some of the striking dietetic ideas of Mrs. Rorer.

MEDICAL COLLEGES AND THE MISSOURI STATE BOARD OF HEALTH.

THE Missouri State Board of Health has passed a resolution which, according to *The General Practitioner*, is "loaded," and is likely "to scatter feathers and fly fur." This resolution is to the effect that, as a condition for the recognition of any medical college in good standing, the colleges shall furnish the secretary of the State Board of Health, on or before January 1st of each year, a complete list of all their matriculates, together with the basis upon which each applicant matriculated, giving the name of the institution from which the degree or certificate of graduation was obtained, or the name of the State official conducting the examination, or the college previously attended, together with the date when the degree or certificate was issued. This list is to be sworn to by the executive officer of the college, and attested by the secretary under the seal of the college.

The object to be accomplished by this resolution is the prevention of students matriculating and only partially attending courses, as well as to prevent the colleges accepting students who have been sent away by other colleges, and we add, in the words of *The Practitioner*, "It will prevent some of the hurrah institutions from lying about their registration list to every student that comes to the city."

BLOOD CHANGES IN DISEASES OF THE STOMACH.

THE changes in the blood resulting from chronic disorders of the stomach have recently occupied the attention of Dr. Blindermann. He has made careful examinations in eighteen cases of this kind, including various affections from gastritis and ulcer of the stomach to advanced cancer. The results of the observations are published in the *Wiener Medizinische Blätter*, October 31, 1895.

The author was unable to discover any hæmatic changes in acute gastric disorders. But in chronic catarrh of the stomach and dilatation some slight diminution in the proportion of hæmoglobin was noticed. Nevertheless Dr. Blindermann expresses his surprise at this, since it is well known that chronic catarrhal affections of the stomach react profoundly on the general health. Without going into the details of the author's observations, his conclusions may be stated in the following propositions:

It is possible to establish a differential diagnosis between cancer of the stomach and the less serious affections of that organ by blood examination.

With rare exceptions the distinction between ulcer of the stomach and carcinoma is greatly facilitated by examination of the blood.

It is especially noteworthy that in cancer there is a

steady diminution in the proportion of hæmoglobin, whereas in simple ulcer this is not observed.

There can be no doubt that gastric affections are often quite obscure, and if the systematic examination of the blood can aid us in arriving at an early diagnosis it clearly should never be omitted. We must remember, however, that Dr. Blindermann's cases are hardly sufficiently numerous to warrant far-reaching generalizations.

CAFFEINE IN DISEASES OF THE RESPIRATORY ORGANS.

ALTHOUGH esteemed by some as of great value in certain cases, the employment of caffeine has always been rather limited in extent. The drug is regarded as a serviceable heart tonic and a diuretic, and also as efficacious in the relief of certain forms of migraine, but this is about the limit of its application. According to Dr. E. M. Skeritt, however (*The Practitioner*, Vol. liv., No. 4), caffeine is possessed of considerable virtue in respiratory affections, especially in those where the element of spasm is prominent. It is in asthma especially that Dr. Skeritt has obtained good results with caffeine, and he believes that the drug is deserving of much wider recognition than it has hitherto obtained in the management of this intractable and erratic complaint. Success does not always attend its use, he says, but its failures are perhaps fewer than those of any other remedy; and he has often remarked that when drug after drug and specific after specific have proved unavailing, caffeine has afforded relief.

The action of the remedy in any individual case cannot be predicated, although as a rule the writer found more certain effects in adults than in children. The results were more uniform also in those cases in which there were no evident sources of peripheral irritation, such as dyspepsia or nasal polypi. The drug was given in five-grain doses, repeated every four hours during the paroxysm until relief was afforded, and then at longer intervals.

But it is not only in asthma that the writer above mentioned has observed good effects from the administration of caffeine, for they are exerted, he says, in any morbid condition in which muscular contraction of the bronchial tubes is a factor, and they are proportionate to the amount of such spasm which is present in any given case. Thus, in acute bronchitis, when the existence of dry râles points to a narrowing of the tubes from contraction of the muscular fibres in their walls, as well as to inflammatory swelling of the lining membrane, caffeine will tend to cause relaxation of the spasm, and consequently relieve dyspnoea in so far as it is due to this element, but there will be no change in the physical signs indicating tumefaction of the mucous membrane or the presence of secretion in the bronchial tubes. There is often an element of true spasm in chronic bronchitis and emphysema: and upon this, Dr. Skeritt says, caffeine will be found to exercise a beneficial influence, allowing greater freedom in the passage of air, thus relieving the dyspnoea and adding much to the comfort of the patient.

Caffeine has occasionally been found of service in

acute respiratory affections where heart failure threatens, as in pneumonia and capillary bronchitis; and it has been especially praised by various observers in the treatment of the former disease. It is also well spoken of in atelectatic and hypostatic conditions of lung. "It is obvious that its action as a heart tonic as well as a relaxer of bronchial spasm makes it doubly useful in many morbid conditions of the respiratory organs; and it undoubtedly gains additional value by its influence as a general stimulant to nerve centres—in cerebrum, in cord, and in medulla."

HARVARD AND THE ADVANCE IN MEDICAL EDUCATION.

THE position recently taken by the Faculty of the Medical School of Harvard University is of great interest to medical educators and to the profession in general. It is a step really in advance of anything that has been done by other colleges, for, though Johns Hopkins has preceded it, Johns Hopkins is not a school that has yet cut any figure in the education of medical students. We believe that the sentiment of the profession will be one of strong approval of the action taken by the Harvard Faculty. It would be unwise, and, indeed, impossible for all medical colleges to imitate this step at the present time, but it will benefit the profession, as a whole, to have in the country institutions adopting so high a standard as that now adopted at Cambridge. We shall expect, not only that this course will be a stimulus to other schools, not only that it will tend to provide a larger number of thoroughly educated physicians, but it will add to the dignity and respect in which the medical profession is held by the world at home and abroad. It cannot be denied that compelling a medical student to get a degree in arts or science before he begins the study of medicine, means that he will have to undertake this study late in life, and that he will not be able to begin the practical work of his profession until he is nearly thirty years of age. Still, we have so many members of the medical profession that the public will not suffer if the newcomers are carefully sifted.

News of the Week.

Dr. Louise Fiske Bryson.—The many friends of Dr. Louise Fiske Bryson will gladly join us in our congratulations on the prospects of a speedy recovery from a recent and severe operation.

Jefferson Medical College.—Dr. George Dock, formerly Professor of Pathology in the University of Texas, and more recently in the Ann Arbor University, has been elected Professor of Pathology and Bacteriology in the Jefferson Medical College.

Manhattan Hospital.—Dr. Rodenstein, the founder of the Manhattan Hospital, and a contributor to the building fund to the extent of some \$12,000, it is said, has been forced to resign by the action of the Board of Lady Managers, in stripping him of his official position of chief of staff. There seems to have been some

misunderstanding between the chief and the head nurse, and while the managers upheld the latter, some thirty members of the board who sided with the doctor sent in their resignations. The name of the hospital has been changed to the "J. Hood Wright Memorial." Mrs. Wright is president of the Ladies' Board.

New York Consolidated Library.—Dr. John S. Billings, formerly of the United States Army, and lately Professor of Hygiene in the University of Pennsylvania, has been appointed librarian of the New York Public Library. This library already has over 360,000 volumes and property amounting to several millions.

Death of an Aged Physician.—Dr. Stephen Van Rensselaer Bogert, ninety-one years of age, once Governor of Sailor's Snug Harbor, died on the 10th instant of old age, at his home in Livingston, S. I. He was a graduate of the Western New York College of Physicians and Surgeons. Dr. E. S. Bogert, Medical Director of the United States Navy, is his son.

Dr. Yeretzian's Murder.—A letter, dated December 9th, has just been received here by Dr. Farnsworth, describing the massacre in Cesarea in which the Armenian missionary, Dr. Yeretzian, who took his medical degree in Philadelphia, was shot down after his house was set on fire by the mob; his wife and son perishing with him in the flames.

A New Healing Serum.—Dr. Marmorek, a young physician of Vienna, after four years of bacteriological research has succeeded in cultivating a healing serum that is not only efficacious in the cure of erysipelas, but is equally so in infectious connective-tissue inflammations, infectious bronchitis, and even in puerperal fever. The serum is a product of the streptococcus, cultivated along the same lines as the antitoxin for diphtheria. The investigations have been made in the Pasteur Institute in Paris, and have been observed with great satisfaction by some of the leading physicians of that city, among whom are Drs. Chautemesse, Bar, Cuffer, Sevestre, Pozzi, and Dieulafoy. Dr. Marmorek is quite satisfied with the results of the injection of this serum, but believes they are more particularly promising in post-mortem wounds and those infectious punctures so often received in surgical operations. This serum in the hands of Dr. Chautemesse gives, for erysipelas, a mortality of 2.59 per cent. based upon 500 cases, as against 3.79 per cent. for 554 patients treated by the most approved methods without serum injections. The general condition improves some hours after the operation; nervous manifestations and especially the delirium are very favorably influenced.

Mount Sinai Hospital, New York.—There is a vacancy in the attending staff in the Medical Department of Mount Sinai Hospital, and applications for the same will be received by the board of directors up to the first of March.

Variolo-Vaccine was opposed as a substitute to Jennerian vaccination by Dr. Hervieux in the French Academy at its meeting of December 24, 1895, on the

ground that being simply the attenuated virus of variola it would always remain an agent to be feared, while on the other hand vaccination has stood the test of time.

Scarlet Fever in Bellevue Hospital and the Island Institutions.—Scarlatina continues to break out among the inmates as well as to attack the nurses and physicians of the hospital, two new cases having developed on the 12th. Three weeks ago Dr. Robbins and twelve nurses were taken to the Willard Parker with the disease, and now Dr. Taft of the surgical staff has joined them. The disease has extended from Bellevue to the city institutions on Blackwell's and Randall's Islands. One of the resident physicians, a nurse, and an attendant have been removed, it is said, to the Willard Parker Hospital.

Obituary Notes.—Dr. Pio Rengifo, who once practised for two years in this city and subsequently in Lima, Peru, died of apoplexy in Panama on January 12th. General Julio Rengifo, Columbian Chargé d'Affaires in Washington, D. C., is his brother. Dr. Abraham M. Lozier, of this city, who retired from practice some eight years ago, died on January 14th of heart disease. He served as surgeon during the Civil War in the army of the Potomac, and was at one time dean of the New York City Medical College and Hospital for Women. Dr. Harriet Kane, of the city of Kane, Pa., died on January 9th, while at church. She was forty years old and had suffered from disease of the heart.

Thrown From His Buggy.—Dr. Levi G. Battdorf, of Avon, Pa., was seriously injured on January 7th by being thrown from his carriage in consequence of his horse taking fright at a train of cars.

Chester Co. (Pa.) Hospital.—The Chester County (Pa.) Hospital has received from Mrs. Sarah T. Johnson, of Philadelphia, a check for \$3,500. This, in addition to a previous donation of \$2,500, is to be applied to the maintenance of a room in the hospital, to be furnished by the same patron as soon as it is ready.

The Manhattan Hospital Bill.—The bill for the transfer of the New York City asylums for the insane to the State, known as the Manhattan State Hospital bill, has been introduced in the Senate by Mr. Cantor, and in the Assembly by Mr. O'Grady. The bill is the same as that which was passed unanimously by both branches of the Legislature of 1895, but which Mayor Strong failed to sign, differing only in change of dates and a few verbal alterations. All reference to the payment by the city of the taxes due to the State for the support of the insane has been omitted, as the Court of Appeals has recently decided this case.

A Fellowship in Anatomy in honor of the late Dr. Leidy is to be established in the University of Pennsylvania.

Banquet of Eastern (N. Y.) Medical Society.—The first annual banquet of the Eastern Medical Society was held at the Central Opera House, New York, on the evening of January 10th. Two hundred guests

were present, including the wives of some of the members. Dr. Browd was chairman. The following gentlemen responded to toasts: Drs. Zwisohn, Valentine, Louis Fischer, Carl Beck, Garrigues, Gottheil, Milliken, Burstein, Browd, and others.

The Harvard Medical Faculty Vote to Require a Degree for Admission.—At a meeting of the Faculty of the Medical School of Harvard University, held January 4th last, the following vote was passed with little less than unanimity:

"In and after June, 1901, candidates for admission to the Medical School must present a degree in arts, literature, philosophy, science, or medicine from a recognized college or scientific school, with the exception of such persons, of suitable age and attainments, as may be admitted by a special vote of the Faculty taken in each case.

"All candidates, whether presenting a degree or not, are and will be required to satisfy the Faculty that they have had a course in theoretical and descriptive (inorganic) chemistry and qualitative analysis, sufficient to fit them to pursue the courses in chemistry given at the Medical School."

In the annual report for 1892 the Dean of the Medical School called attention to the diminution in the proportion of college-bred men who had entered the school since 1884, in which year the maximum of 53.9 per cent. was reached. This diminution went on steadily until in 1892 the ratio was only 28.2 per cent., a ratio which with one exception was less than in any year since 1872. Since 1892, however, the ratio of graduates of colleges and scientific schools generally has been again on the increase, and in 1895 the proportion of students having such degrees as are to be required was 40 per cent.

Annual Meeting of the Massachusetts Cremation Society.—At the annual meeting of the Massachusetts Cremation Society, which was held last week, it was reported that eighty-seven bodies have been cremated at the Forest Hills Cemetery during the last year, which is an increase over the previous year's work. The officers of the previous year were re-elected.

Deaths Under Anæsthesia.—A death is reported as having occurred at Guy's Hospital, from the use of nitrous oxide and ether. The patient was a married woman, aged twenty-six. Another death at Guy's Hospital occurred recently from the administration of chloroform. This case was that of a young woman twenty years of age.

Dr. Jameson, of Transvaal fame, is said to have been for a long time a successful practitioner and the leading surgeon in the country of his adoption.

The New Year's honors bestowed by the British Government upon medical men include six names. None of them are known beyond the limits of the British isles, except, perhaps, Sir Joseph Fayrer.

New Jersey State Board of Medical Examiners.—Dr. E. L. B. Godfrey, of Camden, has been elected Secretary of the State Board of Medical Examiners of New Jersey, in place of Dr. William Perry Watson, of Jersey City, resigned.

Photographing Retinal Impressions.—A strange, not to say marvellous, discovery is reported by Mr. W. Inglis Rogers, in the *Amateur Photographer* of November 22d. Mr. Rogers asserts that he has been able to photograph the retinal image of an object. His first experiment was done alone; the second was in the presence of three other men, one being a physician. A small object, in one case a shilling, in the other a postage stamp, was placed in a good light before the writer, who gazed fixedly at it for one minute; the light was then shut off, and the test object replaced by a rapid photographic plate, at which the author looked steadily for a period (in the second experiment) of twenty minutes, concentrating his thoughts meanwhile wholly upon the image of the object he had been previously fixing. During the substitution of the plate for the last object, the observer's eyes were closed. The plate was then developed in the ordinary way, and reproductions of the psychograms are given in the journal. In the first case, in which a shilling was the test object, the print shows an ill-defined circle on the plate, and in the second, when a postage stamp was employed (and a larger plate used than before), "two impressions were obtained, one from each eye, and at respectively the same distance from each other as the eyes." These impressions (in the reproduction), according to the *British Medical Journal*, bear a distinct resemblance to a postage stamp; more than this we cannot at present admit. These experiments, or similar experiments, can be carried out by any one with a little assistance. The discovery is announced under the head of "Psychography, or Photography without a Camera, the Dawn of a New Science."

St. Mary's Free Hospital for Children realized the sum of \$2,500, as the result of a benefit performance recently given at the Fifth Avenue Theatre.

Unsolved Crimes.—There is a good deal of discussion now as to the number of "unsolved crimes" that have occurred in this city under present and previous police administrations. There are 3,000 doctors in this city, and against every one there is, we venture to say, an average of two unsolved crimes in the shape of stolen overcoats, instruments, books, etc. The census of unsolved crimes against medical property in New York cannot have been far from 5,000 in the last decade. We have never heard of the wonderful detective force under the late inspectors solving any of the humble problems that affect the property of the doctor—who has no "pull."

American Medical Men and American Newspapers.—We learn a great deal from England about Venezuela, New York, and other remote provincial localities. The following interesting bit of news is published in the *Medical Press*: "'Physicians,' as all medical men are grandiloquently called in America, are made the means of bringing in the almighty dollar for American newspaper proprietors. The New York Tribune recently offered a prize of a 'buggy' to the 'physician' who received the largest number of votes in a competition in which the subscribers to the journal were asked to give the name of the practitioner

who in their opinion enjoyed the greatest popularity. At the end of the competition it was found that a 'homeopathic' (American spelling) practitioner was the winner, with 33,000 votes. We are familiar with a similar method of adding to the circulation of newspapers in this country, but so far, in this connection, medical men have escaped the ordeal."

Physicians Shall Not Disclose Confidential Communications.—Mr. Morrill has introduced a bill in the Senate providing that in the courts of the District of Columbia no surgeon shall be permitted, without the consent of the person afflicted, to disclose any information which he shall have acquired in attending a patient in a professional capacity, and which was necessary to enable him to act in that capacity, whether such information shall have been obtained from the patient or his family, or from the person or persons in charge of him; provided that this act shall not apply to evidence in criminal cases where the accused is charged with causing the death of or inflicting injuries upon a human being, and the disclosure shall be required in the interest of public justice.

The Originator of the Quinine Industry.—*The Agricultural Gazette*, of New South Wales, states that there is still living at Kenmore, in excellent health, Mr. Charles Ledger, the man who, forty years ago, after most perilous adventures, introduced the variety of cinchona calisaya known as ledgeriana into the island of Java. Messrs. Howard & Sons, the great quinine firm, say that the supply of Peruvian bark from Java is almost all from the ledgeriana trees, the only complaint against this variety being that it has turned out so rich that the trees are supplying too much quinine for the world to consume. Perhaps the quantity of bark which is now produced every year from seed furnished by Mr. Ledger cannot be short of ten million pounds, and to him, more than any one else, perhaps, is due the fact that quinine has been brought within the means of the very poorest.

The Mysterious Epidemic of 1893, it seems, has again made its appearance near Paris. Its source was then attributed to infected parrots brought from South America. M. Nocard has discovered, it is said, an extremely virulent microbe in the wings of birds which died during the voyage from Buenos Ayres. Mice, fowls, and rabbits inoculated with it died within forty-eight hours, while a healthy parrot, in the bottom of whose cage the dry wings were placed, died within twenty hours. Dujardin-Beaumetz thinks imported parrots may have something to do with the mysterious sickness and deaths which have occurred in the department of the Seine-et-Oise.

Laboratories in Hospitals.—We have frequently taken occasion to say a word against the excess of hospitals and dispensaries and their abuse in this city. Condemnation, even when most deserved, always savors more or less of the rude and unpleasant. It is, therefore, with a feeling of satisfaction that we mention the fact that one of our long-established hospitals (St. Luke's) intends in its new location, funds permitting, to complement its charitable or purely hos-

pital work by enlarging its laboratory and carrying on original research. No doubt all of our large hospitals furnish much material and excellent opportunities for widening and perfecting the healing art, which, under present methods and for want of sufficient laboratory facilities, cannot be fully utilized.

An Unsuccessful Brain Operation.—An interesting case of brain tumor, from Krafft-Ebing's clinic, in Vienna, was recently submitted to operation by Professor Gussenbauer. Jacksonian symptoms developed primarily in the right hand and spread to the arm, lower extremity, and face, followed eventually by aphasia. The severity of the later symptoms gradually diminished, with persistence of the primary focal manifestations. Under these encouraging conditions for the removal of a limited growth in the hand area, the operation was performed. A large area of the left hemisphere was exposed by elevation of a triangular flap of the skull and adherent scalp. No superficial lesion beyond slight congestion was noted. On palpation of the cerebrum, deeply seated resistance was discovered, extending diffusely toward the occipital lobe. In the absence of fluctuation, exploration was not attempted, and further operative interference was abandoned.

The Prevention of Ophthalmia Neonatorum.—

At the last meeting of the Medical Society of the State of New York, a special committee—Drs. Lucien Howe, of Buffalo; Peter A. Callan, of New York; and W. C. Wey, of Elmira—was appointed to call the attention of nurses and midwives to the law regulating their duties in cases of purulent ophthalmia of infants, and to report to the proper authorities cases in which this law is violated. This law is a part of chapter 361 of the Laws of 1892, and reads as follows:

"Being a midwife, nurse, or other person having the care of an infant within the age of two weeks, neglects or omits to report immediately to the health officer, or to a legally qualified practitioner of the city, town, or place where such child is being cared for, the fact that one or both eyes of such infant are inflamed or reddened whenever such shall be the case, or who applies any remedy therefor without the advice, or except by the direction, of such officer or physician," etc.

In New York City, the Society for the Prevention of Cruelty to Children has, at the instance of several physicians, prosecuted cases of violation of the statute. The following are taken from the Records of the Society:

"Case No. 77,605.—Mrs. Minnie Schneider, of 508 East Twelfth Street, attending a child of Mrs. Louis Wageman, of 356 East Tenth Street, was tried for violating this law, was obliged to give bail for \$300, and was fined \$5."

"Case No. 80,156.—Wilhelmina Schenlin, of 457 West Forty-ninth Street, attended a child of Mrs. Mary Wildey, of 507 West Forty-eighth Street, was found guilty of its violation, April 11, 1894, and fined \$25."

"Case No. 81,821.—Anna Kotil, 218 East Third Street, attended a child of Anna Biza, of 120 East Third Street, pleaded guilty, June 22, 1894, and was fined \$100."

"Case No. 94,949.—Fanny Greenstein, 295 Stanton

Street, attended the infant child of Mrs. Kate Daub. The child became practically blind. The midwife pleaded guilty and was fined \$25.

These cases of blennorrhœa of the new-born child were undoubtedly all sacrificed through the ignorance of the attending midwife, and might have been saved had they received prompt treatment. The value of the law of 1892 is here amply demonstrated, and it is a fortunate thing for this great city that the Society for the Prevention of Cruelty to Children stands ready to prosecute offenders under this statute.

Proposed Memorial to Sir Andrew Clark.—Mr. Henry C. Burdett, of London, writes: "The paragraph you publish in your number of December 7th, page 827, under the above heading, contains a quotation from *The Medical Press and Circular*, which cannot in justice be allowed to pass without protest. The quotation runs as follows: 'It would be absurd to ask the general practitioner, who finds a good deal of difficulty in making both ends meet, to subscribe to a memorial to a man who was making £15,000 a year, and who, although immensely rich, left nothing to the London Hospital, to which he owed so much of his success.' Everybody is agreed that Mr. Gladstone's proposal to invite the general practitioners as a body to subscribe to this memorial is impracticable for many reasons. The statement, however, that Sir Andrew Clark, 'although immensely rich, left nothing to the London Hospital, to which he owed so much of his success,' is, I venture to feel and to say as an intimate friend of the deceased physician, a statement unworthy of any respectable medical journal. It is well known that Sir Andrew Clark was struck down by paralysis in the midst of his work, unexpectedly and suddenly; that he was at that time in his sixth year of office as President of the Royal College of Physicians, and that he had every right to anticipate that he had several years of useful life before him. I am confident, in fact I may state that I know, that had Sir Andrew Clark lived to make a distribution of some portion of his wealth among charities, as he undoubtedly intended to do, the London Hospital and other great charities would have largely benefited by his munificence (for he was a liberal giver), and that fate alone prevented him from carrying out this intention. If further proof of this fact be necessary, I would point to the circumstance that when he received £5,000 from a patient for distribution among charities, having already refused it as a fee, he devoted a large portion of it to the London Hospital. I would further remind your readers of the medical profession that the Governors of the London Hospital have officially declared with much force and truth: 'Sir Andrew Clark first came to London in 1853, to join the London Hospital. From that time to the hour of his death he was enthusiastically devoted to its service.' It will therefore be seen that if, as was undoubtedly the case, Sir Andrew Clark owed much to the London Hospital, he was ever ready and willing to acknowledge his indebtedness, and to repay it to the utmost of his ability by the unstinted devotion of his time, talents, and gifts to its service, during forty years of his successful career."

Society Reports.

ASSOCIATION OF AMERICAN ANATOMISTS.

Annual Meeting, Held in Philadelphia, December 27 and 28, 1895.

(Special Report for THE MEDICAL RECORD.)

The Duty of the Medical Profession to Civilization and to Science.—DR. THOMAS DWIGHT, of Boston, Mass., in his opening address as president of the Society, spoke of the horror which the general public have for human dissection, and the aversion of the popular mind to this very necessary part of medical research. This prejudice, he believed, was founded first in the popular belief that sepulchres were violated, and second that the remains were subjected to wanton insult.

"It is idle to hope that, while human nature remains as it is, this aversion to dissection will ever disappear. Our wisest course is to recognize it and to soften it by removing all just cause of complaint. It should be made clear to the public that dissection can and should be followed by decent burial. I, myself, would go so far as to have the bodies of Protestants and Catholics buried in their respective cemeteries when the creed of the deceased is known. It should also be understood that no wanton insult is permitted in reputable schools. . . . The policy which will lead to the most satisfactory results is one of complete openness. Above all we should avoid a timidity which shirks discussion of this topic. When we shall show so clearly as to carry conviction that we have nothing to conceal, a great step will have been taken.

"A radical defect in the laws of many States, otherwise well drawn, is that the delivery to medical schools of unclaimed bodies is optional with superintendents, boards of trustees, and municipal authorities. The result of this is that those in authority very naturally hesitate to do anything for the advancement of science which not only can be of no possible advantage to themselves, but may involve them in serious difficulties."

German anatomists have recently adopted a report, prepared in company with representatives of other European countries, prepared with the idea of establishing a more satisfactory and at the same time more scientific nomenclature than is at present in use. It is for us to decide whether their report is satisfactory, and, if so, whether we shall join hands with our foreign colleagues, or if such is not the case, whether we can devise an American nomenclature which shall be so much better as to be distinctly superior to that at present in use.

Anatomical Material and Preservatives.—The committee appointed by the association to investigate this subject made their report. A circular letter had been sent to the professors of anatomy in one hundred and forty-eight colleges in the United States, twenty-five to foreign countries, and twenty-five copies to the medical journals in this country and abroad. Of the replies received the following is a summary:

1. Anatomical material is received wholly under the provisions of the law in 30 States and countries, in part by law in 7, and without law in 5.

2. The provisions of the law were satisfactorily complied with in 10, fairly so in 10, not satisfactorily in 12, and no replies were received from 10. In 8 the provisions of the law were stated to be obligatory, and in 6 the provisions were optional.

3. The material was received in good condition in 20 institutions, only fair in 21, and in 1 bad.

4. The remains were reported as buried in 27, cremated in 10, and thrown away in 4.

5. Carbolic acid stood first among the preservative agents, glycerin and arsenic next in their order of popularity. All three of these agents were best employed in combination. Chloral hydrate, chloride of zinc, and the bichloride of mercury came next in the order of popularity. Alcohol, either pure or in combination, the carbonate of potassium, the bicarbonate of sodium, chloride of sodium, methyl spirit, formalin, nitrate of potassium, brown sugar, and boracic acid were employed in varying proportions.

Chloride of zinc in a solution of fifty-per-cent. strength and of neutral reaction was found very useful, but it had the great disadvantage of hardening the tissues and causing a change of color. If subjects have been immersed for a long time in a saturated solution of common salt, it has been found advantageous to soak them in water for twenty-four or forty-eight hours in order to soften the tissue.

6. Injections were made in 2 instances into the heart, in 19 into the common carotid artery, and in 6 into the common femoral artery.

7. The cost of reception and preservation varied from \$1 to \$25.

8. The number of students assigned to each subject varied from 4 to 16.

Conclusions.—1. Anatomical material for the promotion of medical study should be obtained wholly under legal enactment. The provisions of the law should be compulsory upon all officers of the State and county institutions and municipal governments.

2. Of the anatomical laws which are in force in this country the committee is of the opinion that the law of the State of Pennsylvania is the best.

3. The committee believes that it would contribute to the best interests of anatomical teaching in this country if concerted action were taken by this association to secure the enactment in every State of a law controlling the collection and distribution of anatomical material, and it heartily recommends such action.

4. While many of the agents employed have been successfully used to a greater or less extent, no perfect method of preservation has as yet been secured. The cold-storage plan, however, approaches nearest to perfection, and some such method will no doubt come into general use when the expense can be reduced. At present the great objection to the use of the cold-storage plan and formalin as well is the great expense involved.

DR. B. G. WILDER, in discussing the report of this committee, said that, after an experience of over twenty-seven years, he was still wedded to the use of alcohol. Brain tissue, he finds, is best preserved by a combination of formalin, bichloride, and salt. For muscles and viscera, alcohol has been found the best preservative. There are two objections to its use: first, the cost, and, second, the property which it has of bleaching the tissues.

DR. G. S. HUNTINGTON agreed fully with Dr. Wilder in regard to alcohol. He recommended, also, the cold-storage plan, which, after an experience of three years, had been found to give good results. Any injection should be made before freezing. Immersion in cold water is the best method of removing the ice from the interior of the body, and hastens the uniform melting of the parts. Arsenite of soda was used chiefly for washing the blood out of the body. Injections were made into the carotid artery, and the blood was allowed to flow until the water which made its escape was no longer tinted with blood.

DR. BEVAN said that he had had excellent results with a combination of cold storage and a preliminary injection of alcohol, glycerin, and bichloride. In handling the bodies while in cold storage, he made use of a pair of tongs, which can be made by any

blacksmith for about a dollar, in such a way as to fit into the external auditory meatus of each side. He has found a solution of formalin and Müller's fluid to be useful in the preservation of brain tissues; the substance so prepared hardens rapidly, and may be used for class demonstration; to within three days the color is well preserved, and it is possible to distinguish the gray and white matter at a distance of fifty feet. He uses a five-per-cent. solution of formalin in Müller's fluid, enough of the solution being employed to immerse the specimen.

Contribution to the Myology of Lemur Bruneus.—DR. GEORGE S. HUNTINGTON, of New York City, read an interesting communication on this subject. He confined his attention to the muscles of the trunk, pectoral girdle, and upper extremity. His results differ in many respects from the descriptions published by Murie and Mivart in their memoir of the Anatomy of the Lemuraidea and others.

The paper dealt especially with the following points, which have heretofore been undescribed:

1. The presence of an axillary arch from the latissimus dorsi to the pectoral insertion, replacing the cutaneous muscular slips described by Murie and Mivart.

2. The arrangement of the pectoral insertion. The peculiarities of the humeral attachment of the pectoralis may be arranged as follows:

(a) Connection as already stated with a slip from latissimus dorsi reproducing the condition found in a distinct variety of the humeral axillary arch.

(b) Connection of the abdominal division of pectoralis major with the pectoralis minor at insertion into lateral humeral ridge.

(c) Folding of insertion tendon of sternal division of superficial pectoral.

(d) Insertion of clavicular portion into superficial aspect of sternal tendon and fusion with deltoid.

All the conditions referred to can be properly regarded as presenting strong simian and anthropoid affinities.

3. The coraco-brachialis presented a division into an upper, middle, and lower part; the latter was inserted into the root of supracondylar arch. The musculo-cutaneous nerve perforated the middle division.

4. The presence of a large and distinct epitrochleo-anconeus from the supracondylar process to the internal condyle and the ulnar margin of the olecranon.

5. The union of the brachialis anticus and the lateral head of the triceps, both extending to the head of the humerus and arising from the outer aspect of the bone.

6. Among the trunk muscles the arrangement of the supracostalis is especially to be noted, extending from the cartilage of the first rib to the third, fourth, and fifth cartilages at their juncture with the sternum.

The entire group of deep thoracic muscles presented a typical carnivore aspect. The supracostalic thoracic extension of the rectus abdominis to the first rib, a continuation of the serratus anticus with the levator scapulae, the thoracic extension of the scaleni group and its relation to the external oblique, all conform almost absolutely with the type presented by a plantigrade carnivore as *Taxidea Americana*. On the other hand the pectoral girdle and brachial muscles conform to the simian type. Thus far *Lemur bruneus* is especially marked in the arrangement of the pectoral group.

In the abdominal-muscle groups the arrangement of the external oblique aponeurosis clearly foreshadows the structures found in the higher primals, especially in relation to the construction of the external abdominal ring, Gimbernat's ligament, and the triangular ligament of human anatomy.

History of the Ciliary Muscle.—DR. FRANK BAKER, of Washington, D. C., read a paper on this subject.

Following the usual description he divided this muscle into two parts, one set of fibres being directed meridionally along the eyeball, and the other set equatorially. The former portion is spoken of as Brücke's muscle or Bowman's muscle, because it is usually supposed that the first description of this part came from one or other of these anatomists. To the second portion has been given the name of Heinrich Müller (Müller's annular muscle), after the celebrated ophthalmologist of Würzburg who described it in 1857. In his lectures on the parts concerned in operations on the eye, published in New York in 1849, Bowman gives a clear description of this muscle. Brücke gave it the name of tensor chorioideæ; of the two descriptions Bowman's is much the best. (Read before the Berliner Physikalische Gesellschaft in May, 1846.) It is to an American, however, Dr. William Clay Wallace, that the credit for priority of description should be given. He described the muscle in *Silliman's Journal* for 1835, eleven years before Brücke or Bowman. The same writer, in his treatise on the human eye published in New York in 1839, again describes it. In a series of lectures which appeared in the *Boston Medical and Surgical Journal* for 1884, he writes of the muscular fibres of the ciliary muscle (see also "Lectures on Myopia," *Boston Medical and Surgical Journal* for 1844, xxx., 288; and the *London Medical Gazette*, 1842-43, i., 412). He supposed, however, that the striations of the orbiculus ciliaris were tendinous. The celebrated copper plates of Eustachius, who lived between 1520 and 1574, gives a description of these parts, which is much more elaborate than is generally supposed. Had it not been for the strange disappearance of these copper plates after the death of this great anatomist, credit would have been given to him for the first description of many structures now ascribed to other observers, such as the Gasserian ganglion, etc. One hundred and fifty years after the death of Eustachius Pope Clement XI. presented these copper plates to Lascisi, who at once recognized their value and caused them to be published. In the explanation of plate 40 of this superb work, the following description appears: "Figura VI. pupillam cum crystallino humore, et ligamento, seu musculo ciliari." This figure plainly shows the radiating ciliary processes surrounding the iris. It was published in Amsterdam in 1722. Fallopius differed with Eustachius and believed that this structure was simply ligamentous.

Plempius ("Vospiscus Fortunatus Ophthalmographia," Amsterdam, 1632, p. 169) describes muscular fibres in the ciliary region. Descartes ("L'Homme de Rene," 1664) reproduces a drawing to show its position. G. Bidloo ("Anatomia Humani Corporis," Amsterdam, 1685) also describes it. William Briggs, ("Ophthalmographia," 1686), ascribes to the muscular fibres found in the ciliary region the property of changing the shape and character of the lens. Porterfield's "Treatise on the Eye," published in 1759, gives many valuable references on this subject, and is referred to by Bowman.

Absence of the Fibrous Pericardium of the Left Side.—DR. ADDINELL HEWSON, of Philadelphia, presented an interesting specimen of this condition, which he had found in the dissecting-room of Jefferson College. The specimen was removed from the body of a man, English by birth, aged fifty-four years, who had been an inmate of an insane asylum for four years previous to his death. By occupation he had been a scrivener. There was distinct absence of the fibrous pericardium on the left side and an adherence between the apex of the left ventricle and the lower anterior margin of the left lobe of the lung. The specimen showed in front the pleura enclosing the internal mammary artery and the left phrenic nerve displaced anteriorly from its normal position. An incision had

been made in the median line to expose the vessels. The aorta practically had no arch and was near the median line. The innominate artery was wanting. The subclavian artery on the left side was found at the highest part of the arch. There was a wide space between the subclavian artery at its origin and the point where it crossed the first rib. The vena azygos major made a very decided arch coursing over the right half of the chest wall.

While the patient had been confined in the asylum he had been in the habit of sitting with his knees drawn up and his head between his knees. This position being the one assumed by him for the most part may account for the adhesions which were present. The course of the phrenic nerve on the left side was normal. The posterior veins were inside of the posterior fold of the pericardium.

Nomenclature of Nerve Cells.—DR. FRANK BAKER, of Washington, D. C., spoke on this subject. He regarded the term, *neure*, as the best phrase to use in describing these cells, because the word lends itself readily to combinations. Thus cells which form nerve roots might be called *rizeneures*, and cells of the cerebro-spinal axis might be called *axoneures*. If necessary these cells can be divided into other groups. Short path cells might be called *zigoneures* or *commissural cells*, and the long path cells of the cortical surface might be called *macro-dromic neures*. In this way sensory fibres might be called *asthesioneures*. Other cells which have their origin in the spinal cord and are especially connected with the muscles might be called *dynamoneures*. . . . The term proposed by Kölliker, or *neurondendron*, is too long. Other neurologists, among them Dr. Fish, prefer the term *neuro-site*. As neurologists and psychologists are giving considerable attention to this subject, it is reasonable to suppose that a better terminology will be adopted than the one now in use.

The Cerebral Fissures of Two Philosophers.—DR. B. G. WILDER, of Ithaca, presented a paper on this subject, which was illustrated by specimens and a number of photographs. The paper referred to Chauncey Wright, of Cambridge, a philosophic writer, critic, and mathematician, and James Edward Oliver, Professor of Mathematics in Cornell University. The brain of the former was very different from the average pattern, and the two brains presented a distinct contrast, probably due to the greater activity and larger breadth of the former's scientific research. The reputation of the former was wider and better known than that of Oliver. One peculiarity of both brains was the simplicity of structure.

The writer called attention to the fact that there was no decided standard of comparison for the normal adult American brain, and he suggested that the members of the Association unite in an effort to secure some such standard.

The Human Paroccipital Fissure—Should it be Recognized and so Designated?—DR. WILDER also read a paper on this subject. Ten years ago the same writer suggested that the occipital portion of the long fissure, called *intraparietal* by Turner, *interparietal* by Ecker, and *parietal* by Pansch, be regarded as a distinct fissure under the title *paroccipital*, referring to its constant and marked relation to the dorsal end of the occipital (*parieto-occipital*). The "U" shaped area between the two or first annectent gyri he proposed to call the *paroccipital gyrus*.

The grounds for this suggestion have been given in the "Reference Handbook of the Medical Sciences," viii., 155, as follows:

(1) In about half the cases examined by the writer there are two fissures separated by an isthmus of greater or less width; (2) when the two are continuous there is always a *vadum* (shallow) at the point

corresponding to the isthmus; (3) each of the two portions, whether separate or continuous, is usually deepest at or near its middle; (4) at their first appearance in the *fœtus* they are always completely independent. While this division is recognized by some observers, it is thought needless by others, and has not as yet received the sanction of the German Committee on Anatomical Nomenclature.

The present paper was intended to review all the accessible literature on the subject, as well as the material accumulated by Dr. Wilder in the interval, especially comparing these parts with similar fissures found in apes and monkeys.

On practical grounds the writer believes that the fissure should be recognized, and called the *paroccipital* division of a "fissural complex." Among eight educated persons the complete isthmus occurred seven times, in all but one on the right side. In only one case did the isthmus occur on the left side and not on the right, and that was the case of an insane Swiss patient.

Practical Histology for Large Classes.—DR. CHARLES S. MINOT, of Boston, presented a communication, in which he said that in Boston they had entirely given up allowing students to make their own preparations, and had found the change to be an advantageous one. Every student is obliged to make a perfect drawing of each preparation, and the drawing is judged on its accuracy. The geometrical faculty is especially developed. In the second half-year they are given practical work, and they then begin the study of the embryo. In commencing the work they are given specimens of the liver, heart, spleen, etc., instead of beginning with a connective tissue, a piece of bone, or the like. It had been found advantageous to teach embryology as a help to anatomy, and as offering an explanation to a great many relations that would otherwise be obscure.

Some Novel Methods of Description of the Human Skull.—DR. HARRISON ALLEN, of Philadelphia, in a paper on this subject, said that his method is to secure a formula for each skull. He begins with the supraorbital ridge, and draws a line between this point and the outer part of the external auditory process. The nasal bone may be divided into three parts, the upper part, the frontal; the main portion, the maxillary, and the third part, the pre-maxillary. In the human skull the third portion is not well defined. The frontal portion is very variable. Holding the bone in such a position as to examine it in profile it is possible to tell the proximal from the distal portion. The latter it is well to call the *radix*, and below that the *salient*. Variations in these portions serve to identify the individual.

In two skulls of Sandwich Islanders which Dr. Allen presented, the one had a well-developed incisor crest and the other had not. . . . The anterior nasal spine is simply the end of the incisor crest. It has received the name of *infantile*, but Dr. Allen prefers the word *pidomorphic*.

The writer believed that the hard palate has not received the attention which it deserves in its posterior part. In negroes the middle lacerated foramen is very much narrowed and is frequently closed.

The temporal fossa may be divided into two parts, the fronto-temporal ridge and the parietal temporal. They are distinctly different. The former is very apt to be closed, and is very rarely continuous with the same line as the parietal temporal. No two skulls show a similar arrangement. In a study of the temporal bone the remains of a suture are sometimes found between the squamous and petrous portion. For the lower portion of this suture the name *retro-tympanic* has been proposed. In speaking of the lacrymal bones Dr. Allen said that scarcely any portion of the

lacrymal bone is in advance of the crest. In the North American Indian and in the Sandwich Islander they are apt to be very small.

Observations on the Fossa Capitis and a Tubercle in the Trochanteric Fossa.—DR. F. J. BROCKWAY, of New York City, presented a carefully prepared paper on this subject. The fossa capitis, which in the human femur is found at the extremity of that bone and gives attachment to the ligamentum teres, presents ordinarily a well-marked depression. In certain of the lower animals this depression does not exist. The ligamentum teres and the fossa capitis are absent in the elephant and hyrax, the rhinoceros and tapir, the hippopotamus, hedgehog, the seal, sea otter, and walrus. They are absent in the monotremes, the echidna, and ornithorynchus, of the marsupials, the great kangaroo, of the edentates, the three and two sloth, and ant-eater. It is also lacking in one rodent, and in one of the insectivora, etc.

While a study of comparative anatomy frequently leads to valuable deductions as to the function of parts of human anatomy, the writer dealt more especially with the human femora. He examined 900 human femora, of which the pedigree of over 400 was known. Moser, in his article in Schwalbe's "Arbeiten," vol. ii., p. 36, says that only one-half of the fossa capitis that he examined presented vascular foramina. Dr. Brockway, however, found that in the 900 adult specimens which he examined, 84 per cent. presented these vascular openings. Twenty-six specimens (2.8 per cent.) presented no fossæ at all, and in 5 cases there was a distinct tubercle in place of a fossa for the insertion of the ligamentum teres. In 5 cases there were double fossæ occurring on one head. In 2 cases there was a combination of a fossa and a separate tubercle on the same head. In 36 cases the fetal condition persisted, *i. e.*, there was a fossa and a distinct postero-inferior groove descending nearly to the margin of the articular surface, and always pointing toward the line passing up from the lesser trochanter to the inferior border of the neck of the femur. Thus it is possible to determine to which side of the body the femur belongs by noting the direction of this groove; holding the fossa facing the observer the groove points to the side to which it belongs.

Twenty-eight cases showed the presence of a fossa and a connected tubercle. The ligamentum teres is not inserted into the whole floor of the fossa, but into its upper half and upper margin. The lower part of the floor is free and the ligamentum teres simply rests upon it. Therefore the vascular foramina are usually confined to the deepest and lowest portions of the fossa. The synovial membrane has a more extensive insertion than the ligament proper. The author described three types of the fossa: first, oval; second, triangular; and third, round. They are all practically the same, whether they contain vascular foramina or not. The most common type of all is the oval form (forty-five per cent.); the next most common the triangular form (thirty-four per cent.), and finally the round type (twenty-one per cent.).

Old people are apt to have shallow fossæ, but their foramina are not more apt to be absent than in adult life. Out of 22 people over sixty, 13 had shallow fossæ. The character of the foramina and fossæ are not symmetrical on both sides. Out of the 900 bones examined only 4 could be called "pilastered." Twenty-eight specimens showed a good third trochanter (three per cent.) not counting an exaggerated gluteal line. Six of these showed also a tubercle in a digital fossa. From a study of these specimens the linea quadrati would seem to be a myth, as Dr. Brockway has never seen it as a distinct line representing the full length of attachment for the quadratus femoris.

A Case of Polyorchis.—DR. D. S. LAMB, of Washington, D. C., showed a colored sketch illustrating this condition. There were three testicles in the right scrotum and one in the left. They varied somewhat in size, but showed nothing abnormal in the texture of each. Three cords could be distinctly seen and felt passing separately through the external abdominal ring. The patient was a male, white, aged forty-five; well developed and enjoyed good health. He was a widower with two children. He has offered to submit to operation if sufficient remuneration was offered.

A comparatively small number of cases of supernumerary testicles have been reported. A number of them, if not the majority, have been questionable. Armstrong, Blumener, Bulaboff, Hauser, Hewitt, Hough, Jacobovics, Kennow, Hetard, MacCann, McElmoil, Mercklin, Franken, Sibbern, Stewart, and Vanchrin, have reported cases. Dr. Hewitt's case seems to be well authenticated and is as follows: The patient was a soldier with two distinct testicles and cords in the left scrotum. The cords united before entering the abdominal ring. This man is alive at the present time, and the condition has existed since birth.

Dr. Lamb also presented a "Note on the appearance of a unilateral tuberosity in place of the trochanteric fossa," with specimen.

The Descriptive Anatomy of the Human Heart.—DR. WILLIAM KEILLER, of Galveston, Texas, read a paper on this subject. The work of Braune and His has within the past decade revolutionized descriptive and topographical anatomy. By a study of the parts in frozen sections their true relations have been arrived at much more accurately than it is possible to do by a study of the organs immediately after their removal from the dead body. Thus, instead of the primitive text-book description of the liver, which describes that organ as having two borders, two surfaces, and no impressions at all, it has now five borders, as many surfaces, and eight impressions. Dr. Keiller uses a solution of gelatin as an injecting mass for the right common carotid artery or the femoral artery.

His description agrees in all essential particulars with His' model. Thus viewed, the heart is an irregular four-sided pyramid, whose base rests on the diaphragm and whose apex has been removed to afford attachment for the ascending trunks of the great vessels. It presents for examination five surfaces (including the base), a number of borders separating these, and the anatomical apex and a clinical apex.

The anterior surface is triangular in shape, slightly convex, directed forward and a little upward. In sagittal mesial section it is parallel with the sternum. It includes the greater part of the right ventricle, portions of the left ventricle, the left auricular appendix, the entire right appendix, and part of the right auricle. It is bound below by the sharp antero-inferior border (*margo acutus*), on the left by the oblique convex and slightly rounded left anterior border (the left border of clinicians), and on the right by the nearly vertical and convex right anterior border (the right border of clinicians). Its superior angle marks the anatomical apex, and here the surface merges in the anterior walls of the aorta and pulmonary artery. Its left inferior angle forms the clinical apex. On this surface are seen the anterior or right coronary artery in the anterior auriculo-ventricular groove, while its marginal branch runs along the antero-inferior border, and in the anterior interventricular groove is the descending branch of the posterior or left coronary artery accompanied by the great cardiac vein. Separated from it by the pericardium are the margins of the lungs and pleura, the sterno-pericardial liga-

ments, triangularis sterni, internal mammary vessels, and sternum.

The right surface is markedly convex, quadrilateral, lies almost vertically, and is directed toward the right. It includes the greater part of the right auricle. Its anterior, posterior, and inferior borders are only slightly rounded, and are therefore fairly well defined. At its superior extremity the surface blends with the wall of the superior vena cava, and at its posterior inferior angle it is similarly related to the inferior vena cava. It is separated by the pericardium from the right phrenic nerve and vessels, the pleura, and inner surface of the right lung.

The left surface is a convex triangular area directed mainly upward and toward the left. It includes about one-half of the free surface of the left ventricle and the left auricular appendix. It presents the proximal extremities of the descending branch of the left coronary artery and great cardiac vein, the marginal and transverse branches of the same artery, and the posterior cardiac and coronary veins. It is separated by the pericardium from the left phrenic nerve and vessels, the left pleura and inner surface of the left lung.

The posterior surface (dorsal surface) is called the base in text-book descriptions. It is four-sided, rather narrower above than below, is convex, vertical, and directed backward. It is formed by the left auricle, and by the portion of the right auricle which joins the two venæ cavæ behind. It presents the openings of the coronary vein (right and left), the great coronary vein and coronary sinus, and the oblique vein of Marshall which runs downward over the surface to enter the left extremity of the coronary sinus. It is only partially invested by the serous layer of the pericardium; it is separated by the pericardium from the bronchi, œsophagus, vagi, descending aorta, vena azygos major, and thoracic duct.

The inferior surface (diaphragmatic surface or base) is quadrilateral, slightly convex, or almost flat when the ventricle contains blood. . . . It is formed by a small portion of the right auricle and the opening of the inferior vena cava; the rest of the surface being about equally divided between the right and left ventricles. . . . In addition to the inferior caval opening it presents the inferior extremities of the right (anterior) and left (posterior) interventricular grooves with the right coronary artery embedded in the former and the coronary sinus in the latter. Crossing it diagonally is the inferior interventricular groove with the descending branch of the anterior or right coronary artery and middle cardiac vein. The posterior cardiac vein runs along its posterior border. The apex of the pyramid is formed by the aorta, pulmonary artery, and superior vena cava. These structures arise from the heart on a level with the upper margin of the third costo-sternal articulation, extending an inch and a half to the left and one inch to the right of the middle line.

The clinical apex is indicated by a point between the fifth and sixth ribs, three and one-half inches to the left of the middle line. The antero-inferior border may be indicated on the chest wall by an oblique line extending from the clinical apex on the left across and slightly upward to a point one inch to the right of the middle line at the level of the sixth chondro-sternal articulation. Along this line the cardiac blends insensibly with the hepatic dulness. . . . On a level with the fourth chondro sternal articulation the area of the heart's dulness extends three inches to the left and one and three-quarter inches to the right of the middle line.

It would seem more consistent with the above description to make certain changes in the cardiac nomenclature. Thus the interventricular grooves are

seen to be superior and inferior, the right coronary artery might be called anterior, and its branches respectively infundibular (as at present), right ventricular (now marginal), and inferior interventricular (now descending); the left coronary artery would be better named posterior, and its branches superior interventricular (now descending), left ventricular (now marginal), and auriculo-ventricular (now transverse).

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 2, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Annual Reports of Officers and Committees.—By the report of the trustees it appeared that eighteen regular and special meetings had been held during the year; the academy building had been kept in repair; several valuable improvements had been made in the engine room, electrical plant, etc.; the building had been kept insured; through the counsel the taxes on the academy for the years 1894 and 1895 had been set aside under the exemption law; the funds had been invested; the new library stack had proved entirely satisfactory; the electric plant had caused a decided saving during the year, and had given more light than the street current had formerly done. The outstanding bonds amounted to \$10,000.

By the report of the Committee on Admissions it appeared that 71 applications had been received, 48 resident fellows had been elected, 13 non-resident fellows, 4 applications had been tabled.

In the report of the Corresponding Secretary it was stated that there had been no foreign correspondence. The report of the Statistical Secretary showed an unusual number of deaths, 22 fellows having died during the year.

Report of the Library Committee.—Different English medical journals on file 80, American 7, French 140, German 167; medical journals in other languages 56; total 650. New books, 2,039. Duplicate copies of books 1,006. Pamphlets, 3,167. Total number of volumes in the library 33,140, being an increase during the year of 2,739. Readers registered during the year 6,574, or 590 more than for the year 1894. The total amount at the disposal of the Library Committee during the year had been \$5,458. A deficit had been left of \$79. For the year 1896 the committee asked for \$5,000, which was \$500 more than had been appropriated in 1895. The committee reiterated what had been said of the necessity for an endowment fund for the library.

Bureau of Nurses.—By the report of this bureau it appeared that the number of nurses who had registered was 103, and the number who had re-registered was 152. Cash received, \$1,237; cash to the credit of the bureau, \$371. Number of nurses sent out, 496.

The Reports of the Treasurer of the Academy and the Treasurer of the Trustees were read by title.

The Council recommended an appropriation of \$4,500 for the use of the library for 1896. The recommendation was adopted.

In accord with a change made in the by-laws the names of fellows in arrears of dues will be posted.

Infantile Intussusception: A Study of One Hundred and Three Cases Treated by Intestinal Distention or Laparotomy.—DR. FREDERIC HOLME WIGGIN read the paper (see p. 73).

Statistics of Intussusception Deceptive.—DR. A. JACOBI, in opening the discussion, said he thought statistics in connection with intestinal intussusception were very deceptive. Compared with the number of cases that really occurred, those which were reported

in the journals, as stated by the author, were very few. He certainly had seen a good many during the forty years which had elapsed since he first published a case, and he had not published another since. This was probably true of other physicians as well. It was probable also that many cases were not seen by the general practitioner; that they, especially of recent years, went direct to the surgeon. This would account for the fact that Dr. Jacobi had seen fewer cases during the past twenty years than before.

Invagination a Preventable Disease.—Dr. Jacobi believed that intestinal invagination was, in a large number of cases, a preventable disease. The healthy intestine was not apt to become invaginated. It was true the possibility was greater in the child than in the adult, for the reason that the attachment of the mesentery and peritoneum in the ileo-caecal region was looser at the earlier period. But this alone was not sufficient reason for invagination except in the few cases where it was aided by violence without previous intestinal disease. One case had been reported in which the invagination had occurred during a violent paroxysm of whooping-cough. Here the cause was purely mechanical, as it was when the intussusception had taken place while jumping the baby up and down in more or less violent manner. But another preventable cause was chronic diarrhœa. An enteritis which was cured early affected only the inner surface of the intestine. But if it were allowed to go on, the deeper layers, even including the peritoneal coat, became involved just as occurred in patches in typhoid fever. The gut in these spots showed grayish-yellow discoloration, was thickened and stiffened, so that invagination was not alone encouraged, but was likely to result in perforations when it did take place. In one of his cases which had come to autopsy he found the tumor and five or six perforations at spots of the kind described. It had occurred in a child two years old who had suffered from diarrhœa both summers.

Regarding treatment, Dr. Jacobi was of opinion that if enemata, properly employed, had no effect within a very few hours, a surgeon ought to be notified. The pressure by enema ought not to be too great. The intestine was not like an iron pipe. Even in the normal condition it would not bear high pressure. But it was frequently diseased, and weaker in some places than in others. Therefore he had long ago given up using the whole length of the fountain syringe, but used pressure of only a foot or two fall. With the baby on its belly, the hips raised, chloroform anæsthesia, that amount of pressure would suffice. He had always advised the use of opiates immediately after reduction in order to keep the bowel absolutely quiet and prevent recurrence.

Improved Statistics Due to Earlier Interference.

—Dr. B. F. CURTIS said that according to some statistics which he had collected in 1887 he had found the mortality-rate from operations in intussusception on both infants and adults to be seventy-six per cent. These statistics, with some which he had collected since, gave a mortality-rate of fifty-eight per cent., which showed a very great improvement. He supposed there had been still further improvement, but he doubted whether the mortality-rate had yet fallen as low as twenty-two per cent. as stated by Dr. Wiggan. Probably few of us would be able to save more than one child in three in view of the late hour at which we were usually called to the case. He thought the improvement noted was due to operating at an earlier period more than to any improvement in operative technique during the past few years, for abdominal surgery had now been at a high standard for some time. Dr. Wiggan's comparison of the cases to those of hernia was a just one, the lighter or reducible cases being likened to cases of reducible hernia, the worst

cases to those of strangulated hernia. The general practitioner should not be refused the privilege of early reducing a hernia, but in doing so he should remember that he was dealing with a surgical case. In intussusception, as in appendicitis, the physician and surgeon should come together as early as possible, for if the surgeon were permitted to see the case in the beginning he would be able to form a better judgment as to an operation. It might be possible at the beginning to determine whether the case were reducible or irreducible. Where there was acute collapse, there should be no delay in operating. On the other hand, if the case developed slowly, rectal injections might be tried.

Regarding relapses, even operative interference did not insure against this, for a number of cases were on record where relapse had occurred after laparotomy, in some within a few hours. Hence Dr. Senn had suggested stitching the folds of the mesentery together in such a way as to prevent intussusception of this portion of the bowel. Dr. Curtis thought that if injections would succeed at all, they would succeed early. If they had to be repeated, it was an indication for operation. He thought a fountain syringe ought to be used, and with an elevation of water of not more than three feet, which was two feet less than what he had formerly thought was permissible.

The operation should be done as speedily as possible. A large opening was not necessary. One sufficient to admit two fingers, or three at most, would enable the operator to make reduction within the abdominal cavity. All unnecessary interference should be avoided. He would advise against resection, especially that by use of suture.

Intussusception Becoming Less Fatal.—Dr. J. LEWIS SMITH thought that during the past twelve years intestinal intussusception had become less fatal than formerly. Twenty-five years ago it was unusual to be called to a case which had not been rendered worse by administration of purgatives at the hands of the parents and physician. He mentioned a case in which a distinguished physician had given half an ounce of quicksilver to a child with a foot of the bowel protruding from the anus.

An early diagnosis was extremely important and could usually be made. One ought to be able to differentiate between dysentery and intussusception within two days at most. In intussusception, after a few hours there was no discharge of fecal matter, but of mucus and blood, with tenesmus. Earlier diagnosis and omission of purgatives would account for the diminished mortality in the last few years. For distention, water was to be preferred to gases. Where peritonitis had spread from the region of the tumor, operation offered little hope.

Does Colicky Pain Mean Intussusception?—Dr. RICHARD VAN SANTVOORD remarked that any one who had made many autopsies on infants must know how frequently small invaginations of the intestine were present. It had been the custom to attribute these to the death agony, but on what ground was not plain. Perhaps it was Treves who had suggested that ordinary colicky pains were due to intussusceptions of the small intestine which came and went. While this was difficult to prove, it had the practical bearing that when one met a case of diarrhœa with colic it was desirable to control it.

Dr. WIGGAN closed the discussion. His objection to the use of opium was that if the intussusception had not been entirely reduced it would cover up the symptoms for a number of hours. If it were given in small doses it would, according to Nothnagel, increase the intestinal peristalsis and thus do harm. The cases cited in his paper had shown the importance of early treatment, for the mortality both from enemata and

from laparotomy had been much higher when there had been procrastination beyond the forty-fourth hour. He did not claim to have presented complete statistics. As far as they went they corresponded closely with Dr. Curtis's, and yet they justified the statement, he thought, that the mortality from laparotomy done within two days should not now be more than about twenty-two per cent. The incision should be a small one. He did not think it was common for recurrence to take place after laparotomy. At the time when he treated his case by enemata he thought it was the proper course to pursue, and although it proved successful, he had been convinced by subsequent study of the subject that it was a dangerous method and should give way to laparotomy.

Officers.—The election of officers resulted as follows: *Vice-President*, Egbert H. Grandin; *Trustee*, J. E. Janvrin; *Members of Committee on Library*, vacancy of four years, H. L. Collyer, term of five years, B. F. Curtis; *Member of Committee on Admissions*, R. A. Murray; *Delegates to the State Medical Society*, Gottheil, Parsons, Richardson, Sayre.

SECTION ON PUBLIC HEALTH.

Stated Meeting, January 10, 1896.

HENRY D. CHAPIN, M.D., CHAIRMAN.

Subject: The Milk Supply of New York City.—

THE CHAIRMAN remarked, after the reading of the minutes of the previous meeting, at which the subject of tuberculosis in cattle was discussed, that a proper sequel would seem to be the discussion of the milk supply of New York City at the present meeting. During the past ten years much had been done to render milk safe as a food, but the steps taken had consisted chiefly in sterilization and Pasteurization. This was good in its way, but, after all, it was not going to the root of the matter, and he believed the opinion was growing in the profession that if we could get good pure milk, and could be assured of its cleanliness and purity, it would not be necessary either to sterilize or Pasteurize, for superheating certainly had disadvantages.

The Present Status of the Milk Supply of New York City.—DR. GEORGE B. FOWLER, health commissioner, spoke upon the milk supply of New York City from a statistical standpoint. One set of charts showed the average receipts of milk from different States, counties, by what railroads delivered, etc. Including milk, cream, and condensed milk, the daily receipts were at least 766,560 quarts. Seventy-eight per cent. of this amount came from New York State, a significant fact as bearing upon the question of legislation, for if the State Board of Health should take steps looking to the supervision of the milk supply from this State it would lead neighboring States to do the same in order not to lose the market. The milk supply came from about 100,000 cows, and he supposed about 90,000 of them were in New York State. The State Board of Health had been allowed only \$20,000 for the payment of salaries and to compensate the owners of cattle killed on account of tuberculosis and of horses killed because of glanders. They had only five inspectors. One could readily see how impossible it was for these to cover the State and how imperfectly the work must be done. The Board should have \$400,000, and should have perfect supervision of all milk coming to New York City. There should be certified milk—certified that the cows from which it had come had been properly tested and were free from tuberculosis. It was proposed to try to obtain such legislation.

The city of New York under the supervision of the

chemical department, or department for foods, was divided into six districts. A chart showed the number of venders of milk in these districts, their business, and the number of quarts which they sold daily. For instance, in one district there were 413 grocers who sold milk, and the whole number of grocers in the city who sold milk was 4,737, while the whole number of whatever business who sold this food product was 6,579, or about 1,000 less than those who sold gin. Another schedule showed that the number of specimens of milk examined during the past year was 99,086, citizens' complaints investigated 166, quarts adulterated destroyed 2,677, arrests 408, trials 364, fines \$12,260, days in jail 87.

The amount of milk from the different counties in the State was not in proportion to their distance from the city, although Orange County furnished the most, 3,000 quarts; many of the counties in almost the extreme west furnished a large quantity, being encouraged by the railroads, which charged the same price for transportation, regardless of distance.

Methods for the Prevention of Sale of Adulterated Milk.—DR. EDWARD W. MARTIN and DR. ERNEST J. LEDERLE, of the Health Department, spoke upon this subject.

Dr. Martin said the city was divided into six districts, and each inspector was supplied with such instruments as a lactometer, thermometer, etc., and with a blank book for recording the date, hour, street, number, business of the dealer, amount of milk examined, its temperature, appearance, etc. If he thought it was watered or adulterated in any way he took a sample, sealed it, and gave a like sample to the dealer, who, if he wished, could have an independent chemical analysis made of it. His own sample was sent to the analytical department, where also a careful record was kept of all the facts connected with the analysis. If there were sufficient facts to justify arrest, a warrant was taken out and the dealer was tried in court and fined. The amount of fines the past year had been over \$12,000. A record was also kept of each dealer. An unusual case was that of one who sold 800 quarts of milk a day, had been fined six times in amount from \$100 to \$250, and still continued in business. The usual form of adulteration was the addition of water or skimming the milk; less frequently some antiseptic, like borax, was added. The inspections were carried on continuously, over 75,000 having been made during the past year of milk at depots, on wagons, in stores, etc.

Method of Chemical Analysis.—Dr. Lederle said chemical analysis of milk was most delicate work, and must be done by a trained analytical chemist. Every step must be watched and noted. The first thing was to see that an average sample was taken. For this purpose the milk must not be acid, else there would be more or less separation of casein; it must not be churned, yet the cream must be fairly incorporated, which was effected by a dozen reversions of the bottle without violent action. Five cubic centimetres were taken up in a pipette and allowed to run into a small flat dish of lead and tin or of platinum, the platinum dish being used when it was intended to test for ash, which required the application of heat. In testing for cream and solids, the dish was placed on a water bath and after evaporation the residue represented the total solids. Of course the weight of the dish, of the milk, and of the difference after evaporation was carefully ascertained. The solids consisted of two parts, fat and solids not fat, such as casein, albumin, milk sugar, and salts. After the water bath came the air bath, temperature not below 100° F. nor above 105° F. In New York the law called for total solids 12 per cent., but it should be higher, as required by some States. At this season of the year it should be 12.5 or 13 per

cent. If it were now desired to determine the amount of ash, the solids just obtained were subjected to a low red heat. The average amount should be 0.75 per cent., rarely falling below 0.7 or rising above 0.8. The addition of water would reduce the proportion of salts, the addition of solids would increase it. The latter was especially true if carbonates were added. If they found increased amount of salts and on adding a strong acid the milk effervesced it showed adulteration by addition of carbonates, for these were not natural to milk.

The test for fats was a delicate one, and was carried out by placing the milk, absorbed in a piece of blotting paper, over boiling ether, all, including siphon, enclosed in a glass apparatus. The vapor of ether dissolved and extracted the fat. The percentage of butter fat required by the law of this city was only 3 per cent.; it should be 3.5 or 4 per cent. The fact that the standard was so low was an inducement to adulteration.

Value of the Lactometer.—This instrument was a form of hygrometer, intended to test the specific gravity of milk as compared with that of water—water represented by 100, milk should not fall below 102; if it fell to 90 it indicated 10 parts water, if to 75 it indicated 25 parts water. A fair sample must be obtained, and the lactometer must not be dropped into it, but allowed to gently settle until it floated. Removal of cream increased the specific gravity; addition of water decreased the specific gravity. For this reason the instrument had been severely criticised, but there was not the least necessity for being deceived by these facts. If cream were taken away, thereby increasing the specific gravity, less fat would adhere to the instrument, which would come away cleaner, without the white color of normal milk. If, further, water were added to raise the specific gravity, these points would become more striking, so that no tyro would hesitate in saying the milk was adulterated. In using the lactometer one was not required to shut out his senses and judgment.

The lactoscope was used for estimating the amount of butter fat contained in the milk, being constructed on the principle that pure milk was less transparent than watered milk. Then came an optical test, watered milk looking blue, rich milk looking white.

The Centrifugal Machine.—A most important instrument for rapid measurement of the fat of milk was the centrifugal machine, the health office making use of a Danish model, while that most employed in this country was the Babcock. By the one shown twenty samples could be tested at once, and only about ten minutes' running of the machine was required. It was a much quicker test than the analytical, was sufficiently accurate, and was accepted in the courts of some States, but as yet not in New York.

The Significance of Micro-Organisms in Milk.—DR. ROWLAND G. FREEMAN read a brief paper bearing this title. Sterile milk could be obtained from the healthy udder by the introduction of a sterile catheter. Bacteriological examination of milk furnished this city showed it teeming with micro-organisms, numbering from hundreds of thousands to millions to the cubic centimetre. They could be classed as pathogenic and as non-pathogenic. The non-pathogenic, however, had a deleterious influence in hastening fermentation and perhaps in producing diarrhoeal and other troubles. They got into the milk from the hair of the cow, the udder, the hands of the milkman, the dust about stables, from unclean pails. In other words, the reason why our city milk contained so many germs was that it came from dirty cows, kept in dirty barns, milked by dirty men, the milk transported in dirty vessels, churned for hours or days by the motion of cars and wagons, during which time the

germs multiplied. When the milk was drawn by a clean method, cooled rapidly, and delivered within twelve hours, it usually contained only one hundred thousand bacteria, contrasted with millions in the other case.

The same methods which favored contamination with non-pathogenic bacteria acted in the case of the pathogenic variety. Besides, the tubercle bacillus was apt to be contained in the milk independent of contamination, if the cow were tubercular. Many epidemics of typhoid fever, diphtheria, foot-and-mouth disease, etc., had taken place through milk, although positive proof was difficult to obtain because the sample for examination was usually taken after the infection and not at the time.

That which most concerned us this evening was transmission of tuberculosis through milk. It had been estimated that seventy per cent. of all the cattle in the State were tubercular, and recent research, he said, went to show that the milk of tubercular cattle, even when the udder was not known to be diseased, contained tubercle bacilli. Unless present in large numbers it was difficult to find them. Positive results could not be obtained by inoculation until after a month. The tuberculin test showed infection of cows which appeared healthy on physical examination. He thought tuberculin might now be made use of in this State, properly regulated by law, to obtain a safe supply of milk.

The Results of Certifying Milk.—DR. HENRY M. CORT, of Newark, spoke of a plan of obtaining certified milk, carried out by Newark physicians, and of its practical results. He had first tried to obtain a better supply of milk for his State by appealing to the State Medical Society, the State Board of Health, and Commissioners of Agriculture for their influence on legislation. Receiving only discouragement, he formulated a plan which provided for a contract between a committee of physicians and a responsible dairyman whereby a limited supply of milk could be furnished a limited area. The physicians were to have no financial interest in the undertaking, while the dairyman was required to carry out the instructions of three or four experts relating to cleanliness, food, etc., and to certifying the milk. Financially, for the dairyman the scheme had been a success: for two years ago he was turning out only 600 quarts of uncertified milk a day, while at present he was selling to the patrons of these physicians over 2,000 quarts of certified milk daily. Moreover, it had led to raising the standard of the general supply of milk of Newark. Scientifically the results had not yet been sufficiently determined, but in the diarrhoea of infants there had been improvement, something had been determined with relation to the constituents of the milk and the chemistry of the food, and the number of bacteria in the milk had been reduced from over one hundred thousand to the cubic centimetre, the number for a fair milk supply, to a few hundred on special occasions, and to a comparatively small number constantly.

This method of certified milk was being duplicated in Buffalo, and was likely to be copied in other cities. It was highly promising.

The Bacillus Coli Communis in the Mouth.—At a recent meeting of the Therapeutical Society of Paris, Dr. Gembert gave the results of a number of bacterioscopic examinations of the mouth. In 60 healthy persons examined, the bacillus coli was found in the mouth in 27 instances, that is to say, 45 per cent. The tonsils appear to be the chief locality in which the bacilli are to be found. In 36 investigations made for the purpose of determining this point, in no less than 19 cases the bacillus was detected, or 52.7 per cent.

Progress of Medical Science.

Pilocarpine as a Prophylactic in Diphtheria.—Some ten years ago the use of pilocarpine was advocated by a number of more or less enthusiastic observers as a curative agent in diphtheria. But the vaunted specific effects of this drug were not sustained by the general verdict of the profession. A Hungarian physician, Dr. Sziklai, has again taken up the jaborandi alkaloid, and on the strength of his observations recommends it in the *Wiener Medizinische Presse* as an efficient prophylactic in true diphtheria, as well as in pseudo-diphtheritic affections and croup. He urges the employment of pilocarpine more particularly in families where one case of diphtheria has already appeared, and he evidently prefers its use to that of antitoxin. He believes that pilocarpine may actually prevent the formation of false membranes. As a safe prophylactic he advises a one-per-cent. solution to be given in ten-drop doses three times a day. For infants less than one year old, half this quantity is sufficient. Dr. Sziklai has never observed any untoward effects from pilocarpine, and believes its use in diphtheria will yet come to be regarded in the same way that quinine is looked upon in malaria.

Nitrite of Amyl in Pneumonia.—Dr. Hayem recently read a paper upon the use of nitrite of amyl in pneumonia. He says this drug can be given in much larger doses than is usually believed, for he has more than once given from fifty to one hundred drops to be inhaled at once, without meeting with any dangerous symptoms. The following is his method of exhibiting the remedy in pneumonia (*Medical Press*): Fifteen drops were poured on a compress and inhaled in the recumbent position without effort; a few seconds afterward the same dose was renewed, and yet fifteen drops more, so that in the space of five minutes about fifty drops were inhaled. The effects produced are those of nitrite of amyl: redness of the face, acceleration of the pulse, precipitation of the respiratory movements. These phenomena soon give place to a slight cough, a thready pulse, dyspnoea, lividity of the face, and cyanosis of the extremities and of the lips. In ordinary cases only one series of inhalations was given daily, while two (morning and evening) were ordered where the symptoms were grave. It did not appear to M. Hayem that the treatment had any marked effect on the duration of the malady, or on the thermic cycle; the effects seemed to have been entirely local, consisting in a decrease of the dyspnoea, a modification of the expectoration, and in an attenuation of the stethoscopic signs. The nitrite of amyl did not destroy the virulence of the pneumococci; its chief influence was on the pulmonary circulation, producing a strong flux which facilitated the return of the blood into the alveolus and hastening the absorption of the exudation. During the last two years the speaker treated seventy-seven cases of pneumonia, with sixteen deaths, by inhalations of the nitrite. Several of the fatal cases occurred in hard drinkers.—*Jour. des Praticiens*, 1895, p. 254.

Living Tissues Cannot be Disinfected.—Dr. Hænel asserts as the result of experimental researches that it is not possible to disinfect living tissues by chemicals. He thinks the best way to treat infected wounds is by free drainage and open dressings. His experiments were conducted on forty-four guinea-pigs. The wounds entered the muscular tissues and were infected by tampons containing a virulent fluid, having in it both streptococci and staphylococci. The tampons remained in for times varying from four to eighteen hours. The wounds were then washed out and dressed

with solutions of either three-per-cent. carbolic acid or six-per-cent. of sodium chloride, and were then dressed with tampons and moist gauze dressings soaked in the respective solutions. Six cases were dressed with aseptic dressings without tampons. Under conditions as similar as possible no distinction was found between the course of healing, whether carbolic acid or sodium chloride had been employed in the solutions. If the virulence was marked, the animals died of acute infection.—*Deutsche Medicinische Wochenschrift*.

The Radical Cure of Hernia in Children.—Dr. Broca, of Paris, has performed the radical operation for the relief of hernia in children under fifteen years of age in 450 cases. Only one death occurred in this series of operations, and this was due to septic peritonitis. Of the total number of cases reported, 14 were umbilical hernias. The others were inguinal hernias, 41 in girls and 395 in boys. Dr. Broca urges that, whenever possible, the operation should not be performed until the infant has been weaned. But operations for strangulated hernia have been successfully done on infants a few days to several weeks old. The technique of the operation is the same as in adults. The time needed for its performance is generally only about ten minutes.—*Lyons Médical*.

Stone in the Bladder and Pregnancy.—A case of large vesical calculus complicating pregnancy has been observed by Dr. Rosenfeld. The woman, aged twenty-seven, was four months pregnant. She had retention of urine and was complaining of severe pain in the bladder. A large stone was found obstructing the urethra. Trendelenburg's operation was promptly performed. It was found that the stone was so bulky that the incision had to be prolonged down to the neck of the bladder. There was free hemorrhage. Abortion took place two days after the operation, and the patient died of complicating pneumonia. At the autopsy peritonitis was not found, but the woman had pyohydronephrosis.—*Munchener Medicinische Wochenschrift*.

False Lupus in the Nasal Cavity.—Dr. Simonin has recently made an elaborate study of so-called lupus pseudopolypus. His conclusions may be briefly summarized as follows: The pathological condition generally described as lupus pseudopolypus is not a true variety of lupus, but a rare form of tuberculosis. The virulence of this form of tuberculosis is, however, less pronounced than that of any other variety. The proper treatment for this affection is purely surgical. The growths are to be removed by the wire snare or curette, followed by cauterization.—*Deutsche Medizinische Zeitung*, December 23, 1895.

Melancholia Following an Attack of Cholera.—That cholera may result in various psychoses is a well-established fact. A Russian physician has recently observed a case of pronounced melancholia in a young man, aged nineteen, who had just recovered from a moderately severe attack of cholera. The patient had to be sent to an insane asylum, where appropriate treatment resulted in complete recovery in less than five months.—*Deutsche Medizinische Zeitung*, December 23, 1895.

Unilateral Weeping in Facial Paralysis.—A case of this kind has been recently observed by Dr. Francke, of Greifswald. It proved conclusively that the facial nerve is the secretory nerve of the lacrimal gland. If, as in the case recorded, the secretion of tears is entirely suppressed, the seat of the lesion must be central and near the ganglion geniculi. On the other hand, if lacrymation is not interfered with, the lesion is sure to be peripheral.—*Schmidt's Jahrbücher*, December 15, 1895.

Pyogenic Action of the Gonococcus.—After a catheterization in a man with gonorrhœa a chill was followed by four intramuscular abscesses situated near the shoulder-joint, popliteal space, inner aspect of leg, and above the malleolus. Culture of the evacuated pus upon serum-agar showed a pure growth of gonococci.—Bujwin, *Centralb. f. Bakt. und Parasit.*, vol. xviii., No. 15.

Aural Vertigo.—Relief was afforded by the subcutaneous injection of pilocarpin nitrate in one-per-cent. solution, the equivalent of gr. $\frac{1}{16}$ being administered before breakfast, the patient remaining abed till the sweating had ceased.—LEMAIREY, *Ann. des Mal. de l'Oreille*, etc., vol. xx., No. 11.

Sexual Tuberculosis.—Primary tuberculosis of the genital organs in both sexes is indisputable, and the presence of bacilli in the genital secretions is possible, so that infection may take place if they come into contact with the mucous membrane of the genital tract. Tuberculous foci in the genital tract of tuberculous individuals are rare, and as infection probably takes place only when such foci exist, it must be of uncommon occurrence, though it may exist without symptoms for a long time. Investigation has shown that transmission in sexual intercourse is possible even in the absence of genital tuberculosis.—DOBROKLOUSKI, *Rev. de Tuberc.*, 1895.

Actinomycosis.—This disease differs in man and animals. In the former the lesions are associated with suppuration; in the latter there are small hard tumors resembling sarcoma. The micro-organism in each case is identical. In man the lesions are most frequent upon the neck in the form of an abscess containing yellow granules (the parasite). This has resulted from a round-celled growth provoked by the parasite, some of the cells having undergone degenerative changes. The tendency is toward the surface, but the deeper tissues are also invaded. The growth in the lungs is either peribronchial or intrapulmonary, and varies in size from a millet seed up to a cherry or even an apple. In the alimentary canal, if superficial, the parasite invades Lieberkühn's glands, forming plaques; if deeper, the results of its penetration may simulate appendicitis. It often begins behind the angle of the jaw in the neighborhood of a carious tooth, forming indurations and subsequent fistulae. In the apex of the lung it may pass for tuberculosis. The chest wall may be invaded.—CHOUX, *Archives Générales de Médecine*.

Complications of Soft Chancre.—Balzer mentions two varieties of gangrene. The first is a reddish, ecchymotic phlegmonous gangrene; the second a blackish form. In the first, the pyogenic organism is present; in the other form, the septic vibrio of Pasteur is found. In this latter form, the disease spreads rapidly; general symptoms are marked, so much so that the patient seems to be in typhoid state. Fournier has made mention of another form of gangrene as the fulminating form. One cannot always find the point of departure of the lesion. Finding the gangrenous condition, it is best to incise the prepuce. If the sheath be found gangrenous, scarify it in many places. Then apply antiseptic dressings. Balzer speaks of phagedena, complicating the soft chancre, as being itself a large, soft chancre, which has arisen from improper care and developing in patients who present favorable conditions for growth, as the alcoholic, cachectic, etc. Symptoms are the same as are those of soft chancre, except they are more intense. The extension is usually on the surface and serpiginously rather than deeply into the tissues. It is slow in progress, with improvements and relapses at times. Cachexia develops, and patient

is depressed. Treatment should be tenacious and unceasing. Balzer mentions cold baths, cauterization with chloride of zinc, with crystals of carbolic acid, iodoform, aristol, etc. Fresh air, good food, and hygienic surroundings are of great importance. Bubo, which is so frequent a complication, may be caused by pyogenic microbes or by the microbes of the soft chancre. Diagnosis is to be made from the ordinary adenitis by the appearance of the pus. In the syphilitic lesion, the pus is usually phlegmonous, thick, and the bacillus of Dueret may be found. Pus that is creamy and serous is more often non-specific. The treatment in these cases is rest, cold applications, tincture of iodine, mercurial ointment, antiseptic injections into the bubo, as of nitrate of silver. The bubo may be excised, the surfaces curetted, and then deep sutures taken.—*Journal des Maladies Cut. et Syph.*, 1895, p. 405.

Poisoning Due to Applications of Bismuth Subnitrate.—M. Gaucher and M. Baki, at a recent meeting of the Société des Hôpitaux, gave an account of several cases of poisoning manifested by a stomatitis and a streak on the gums analogous to that of plumbism; also manifested by slate-colored patches resembling tattooing on inner surface of the cheeks, on the tongue, and on the gums. Also present were symptoms of more or less acute stomatitis with swelling of the buccal mucous membrane.—*Gazette Médicale de Paris*, December 7, 1895.

Pylephlebitis and Abscess of the Liver Consecutive to Typhoid Fever.—Lannois reports such a case, pus from both associated changes showing the bacilli of Eberth. From a pathologic point of view three varieties of abscess are to be recognized: (1) Metastatic, the abscess originating from a focus of suppuration in some distant part of the body, especially in the subcutaneous tissue; (2) from typhoid ulceration of the biliary passages; (3) in consequence of pylephlebitis, secondary to the intestinal lesion.—*Revue de Médecine*, 1895, No. 11.

Treatment of Chronic Urethritis.—J. Janet goes into detail in his article and holds that it is of the greatest importance, before resorting to any instrumentation, to observe the following: 1. To search for the presence of gonococci, to locate their habitat, then to suppress the gonococcus completely. We must rid the urethra of the gonococcus if we wish to avoid accidents not infrequently set up by instrumentation, as an epididymitis. This is comparatively easy by means of large irrigations of entire urethra with warm solutions of permanganate of potash, preceded by massage of prostate and urethra to empty the follicles. Fistulous tracts are to be opened and scraped. Irrigations should be continued ten or twelve days, when search should be made for the gonococcus. 2. To suppress so far as possible the secondary infections, other microbic invasions, which are often engrafted on an old gonorrhœa, and continue after the gonococci have disappeared; then to take measures that these do not return, or are kept down. To suppress the secondary infections is often difficult, because they are not easily reached by the irrigations. The method for this is to use irrigations of bichloride of mercury, 1 to 20,000, for entire urethra and bladder, then instillations of silver nitrate and copper sulphate. The bichloride of mercury may be used in conjunction with the permanganate of potash. 3. After this the urethra or bladder symptoms may be treated according to the lesions left behind and the means appropriate to them. Treat the urethral lesions by endoscope, sounds, massage of urethra and prostate, etc.—*Ann. des Mal. des Org. Gén.-Urin.*, 1895, p. 481.

Correspondence.

OUR PHILADELPHIA LETTER.

(From our Special Correspondent.)

THE AMERICAN PSYCHOLOGICAL ASSOCIATION—ASSOCIATION OF AMERICAN ANATOMISTS—VITAL STATISTICS OF PHILADELPHIA—FUNCTIONS OF THE NEURON—ELECTION OF OFFICERS OF COLLEGE OF PHYSICIANS—IRVING BENEFIT FOR JEFFERSON MATERNITY HOSPITAL—ASSOCIATION FOR THE EMPLOYMENT OF THE INSANE—ELECTION OF OFFICERS OF AMERICAN PHILOSOPHICAL SOCIETY.

THE several visiting scientific bodies brought their sessions to a successful close on Saturday, December 28th.

At the concluding session of the American Psychological Association a discussion on the subject of "Consciousness and Evolution" was participated in by Professors William James, E. D. Cope, J. M. Baldwin of Princeton, C. S. Minot of Harvard, G. T. Ladd of Yale, G. S. Fullerton of the University of Pennsylvania, J. H. Hyslop of Columbia, and Drs. D. S. Miller of Bryn Mawr, and Wesley Mills of McGill. Prof. W. R. Newbold reported "A Case of Dream-reasoning."

Before the Association of American Anatomists Dr. B. G. Wilder, of Cornell, described the "Cerebral Fissures of Two Philosophers." One of the brains was that of Chancey Wright, of Cambridge, and the other that of James Edward Oliver, of Cornell. The following officers were elected for the ensuing year: *President*, Dr. Frank Baker, of Washington, D. C.; *First Vice-President*, Dr. B. G. Wilder, of Ithaca, N. Y.; *Second Vice-President*, Dr. F. J. Shepherd, of Montreal, Canada; *Secretary and Treasurer*, Dr. D. S. Lamb, of Washington, D. C.; *Delegate to Congress of American Physicians and Surgeons*, Dr. Addinell Hewson, Philadelphia; *Alternate*, Dr. D. K. Shute, of Washington, D. C.; *Executive Committee*, Dr. A. S. Bevan, Chicago; Dr. Theodore N. Gill, of Washington, D. C.; Dr. George S. Huntington, of New York City, and the President and Secretary, *ex-officio*.

For the week ending December 29, 1895, the total number of deaths in Philadelphia was 445, a decrease of 29 as compared with the previous week. Of the whole number 159 occurred in children under the age of five years. One-third of the mortality was due to affections of the throat and lungs. There were reported 90 cases of diphtheria and 15 deaths, 25 of scarlet fever and 2 deaths, and 39 of typhoid fever and 4 deaths. For the year the total number of deaths was 23,797, as compared with 22,680 during 1894. Of the whole number 5,487 occurred in children under the age of one year; 1,411 between one and two years; 1,503 between two and five years. The largest number of deaths were attributed to "inflammation of the lungs" (2,582); and the next largest to "consumption of the lungs" (2,449). After these come disease of the heart (1,424), cholera infantum (1,126), marasmus (1,031), diphtheria (1,020).

The Board of Health has adopted a resolution directing that all midwives, nurses, and others having the care of new-born infants be required to report cases of sore eyes within six hours after discovery, according to the law "for the prevention of blindness." The Clerk of the Bureau of Health will keep a record of all cases reported, and will send to every nurse reporting a case circulars giving directions for the treatment of infants' eyes.

Dr. Samuel G. Dixon has been elected President of the Academy of Natural Sciences, Dr. Edward J. Nolan, Recording Secretary, and Dr. Benjamin Sharp, Corresponding Secretary.

At the stated meeting of the College of Physicians on January 1st, Dr. F. X. Dercum read a paper "On the Functions of the Neuron, with Especial Reference to the Phenomena Presented by Hysteria," in which he contended that the neuron (including the cell-body and its processes) has functions other than a merely trophic one, and that it has the property of mobility, which is manifested in accordance with its state of functional activity and fatigue and its nutritive condition. To derangements of the normal relation of the several parts of the neuron with other portions of the nervous system, it was argued, are to be attributed various morbid states and conditions. The annual election resulted in renewed choice by the college of Drs. J. M. DaCosta and John Ashhurst, Jr., as President and Vice-President respectively. Dr. Thomas R. Neilson was elected Secretary; Dr. C. W. Dulles, who had served in this capacity so efficiently for six years and declining to serve again, was, together with Dr. F. A. Packard, elected to Council. Dr. William Hunt retired from the Board of Censors and from the Committee on Müller Museum, his place on the former being taken by Dr. A. V. Meigs and on the latter by Dr. George B. McClellan. Otherwise there were no changes in the elective positions. Dr. P. S. Donnellan and Dr. Henry Toulmin were elected to Fellowship, and Dr. Ernst Leyden of Berlin, and Sir T. Grainger Stewart of Edinburgh, to Associate Fellowship.

Dr. George Dock, Professor of the Practice of Medicine and of Pathology in the University of Michigan, has been elected Professor of Pathology and Bacteriology in Jefferson Medical College. Professor Dock is a graduate of the University of Pennsylvania, and was formerly Professor of Pathology in the University of Texas.

At a recent theatrical performance given by Sir Henry Irving and Miss Ellen Terry and their company for the benefit of the Jefferson Maternity Hospital more than \$3,000 was realized.

It is announced that of 76 applicants for license to practise medicine in Pennsylvania, examined by the State Board a short time ago, 22 failed to make the required average and were refused the license.

Application is about to be made for articles of incorporation for an "Association for the Employment of the Insane," which was organized several years ago by a number of charitable women who undertook to relieve the monotony of life experienced by the insane women at the Philadelphia Hospital by giving them needlework to do.

Dr. Leonard Pearson has been appointed by the Governor State Veterinarian at an annual salary of \$2,500.

At the annual election of the American Philosophical Society held January 3d, Dr. William Pepper was elected one of the Vice-Presidents, Dr. J. Cheston Morris one of the Curators, and Drs. Charles S. Wurts and Henry Hartshorne Councillors for three years.

THE GROWTH OF TUBERCLE BACILLI IN ACID MEDIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of December 21, 1895, appeared an article on the "Chemical and Experimental Research in Antiphrisis" (Klebs), by Drs. Trudeau and Baldwin.

The principal deduction drawn from their experiments is the following: "Since cultures of the tubercle bacillus become acid as they grow, and, furthermore, since the addition without heat of a little alkali to a filtered culture medium, upon which bacilli have ceased to grow, renders it again fit for the development of a

second crop of germs so long as any nutriment remains, it may be inferred that the limitation of the growth of the tubercle bacillus in such a culture medium is most likely due to the acidity induced in the medium, rather than to any specific germicidal substance produced therein."

According to the recent researches of Sander, confirmed by Lubinsky, in an article on "The Methods of Cultivation, Biology, and Morphology of the Tubercle Bacillus,"¹ this deduction of Drs. Trudeau and Baldwin is entirely erroneous. It is contrary to the accepted view to assert that the tubercle bacillus requires for its growth a slightly alkaline, or at least a neutral, medium. Lubinsky verifies the observation of Sander, who states that an acid reaction does not in the least interfere with the growth of this organism.

The tubercle bacillus grows upon non-neutralized potato-meat-pepto media (bouillon and agar) the acid reaction of which is caused by the acidity of the potato and meat, just as well as upon the same media possessing a weakly alkaline reaction; and the bacillus of aviary tuberculosis alone is exempt from growth upon acid media.

Among other enumerated characteristics of this acid medium is that the virulence of the cultures is reduced to one-half the strength of the ordinary tuberculosis cultures; as is proved by guinea-pigs dying in forty to forty-two days after intra-peritoneal inoculation.

JOSEPH MUIR, M.D.

34 WEST THIRTY-THIRD STREET,
NEW YORK, December 30, 1895.

A CHEMICAL AND EXPERIMENTAL RESEARCH ON ANTIPHTHISIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: From a paper by Drs. Trudeau and Baldwin, purporting to be "A Chemical and Experimental Research on Antiphthisin (Klebs)," and published in the MEDICAL RECORD on December 21, 1895, it appears that these gentlemen have attempted to produce "antiphthisin," a substance which I have separated from the mature tubercle culture, and having obtained something which they believed identical with my product, they proceeded further to control my experimental work, as recorded in my book, "Die causale Behandlung der Tuberculose," by the use of their own product.

While the undertaking is commendable, I regret that they apparently failed in both directions, which may be readily accounted for by the facts to be presently stated, most important among which is that they did not strictly follow my methods, a condition which every fair-minded person must concede to be absolutely essential.

Their failure may, in the first place, depend upon their cultures, and next upon the various steps in their treatment of the culture fluid. I may here only point out that in my labors upon the self-limitation of tubercle cultures, I have shown that when the culture fluid is prepared so that it affords the best conditions for the growth of tubercle bacilli, it remains alkaline, and that the culture eventually ceases to grow and dies out, while the culture fluid is still alkaline and before its nutrient substances are exhausted. Only such have I considered as fully mature, and only such have been used by me for the production of antiphthisin. The investigations made by me at that time showed my matured cultures to have invariably preserved an alkaline reaction, and, in connection with the statements in the paper referred to, I have again examined a number of matured cultures, some of them planted two and three months ago, and they are alkaline in reaction.

We know, indeed, that tubercle bacilli can also be made to grow upon neutral or acid media, and in this Drs. Trudeau and Baldwin have evidently succeeded, but they have also shown that acid cultures are probably unsuitable for the production of antiphthisin.

A further proof of the shortcomings of their efforts, whether due to the use of immature acid cultures or to faulty chemistry, appears from their statement that they were able to precipitate all albuminoid substances from the culture fluid with sodic iodide of bismuth. If their culture fluid contained the substance which I have described, its precipitation could not have occurred, unless under the grossest errors, which I will not presume to have been committed.

In this connection one may think of mechanical precipitation, since NaBiI₄ in acid solution is, of course, precipitated when added to water, and E. Brücke availed himself of a similar method, by using cholesterol dissolved in chloroform, for carrying down pepsin.

Repeated precipitation of antiphthisin with alcohol from a watery solution must of necessity diminish each time the quantity recovered, since antiphthisin is freely soluble in water, and according to the degree of percentage of absolute alcohol, more or less antiphthisin must remain in the filtrate, and is therefore lost.

In the past two or three years I have so frequently had occasion to make this precipitation that it seemed gratuitous labor to repeat it; it was done nevertheless, with the expected result, that antiphthisin was obtained from the filtrate as usual.

Drs. Trudeau and Baldwin state, however, that their finished product responded to the biuret test, giving a distinct rose color, which reaction constitutes a further proof that they did not produce antiphthisin, or at least not in a pure form, since my product gives no such reaction.

I believe I have made it plain enough that the experimenters have not produced antiphthisin, and it is therefore useless to examine their causes for failure in the animal experiment. In reference thereto I wish, however, to observe that they seem equally faulty.

In their attempt to repeat my experiment for destroying the tubercle bacillus, or its virulence, in vitro, the experiment was not made as described and practised by me. My procedure consisted in treating tubercle bacilli with one hundred per cent. tuberculocidin, plus two per cent. erethin, for six days before infecting the animals therewith; whereas Drs. Trudeau and Baldwin used their own product, of, to say the least, doubtful quality; they left out the erethin, and infected animals after it had been standing for only six hours!

In regard to the employment of their product, or of my own, for its therapeutic value in experimental tuberculosis, I may also point out what I expect to show more fully in a forthcoming report on this subject, that the obtaining of success in this direction is not so simple a problem that, regardless of the degree of infection or of most painstaking clinical observation and watchfulness, we have only to inject increasing quantities of the remedy every "two or three days," and then obtain a cure! The experimenters seem to have overlooked, or failed to fully appreciate, that my infections were different from theirs, inasmuch as I purposely used tubercular tissue from animals previously treated, but in which I had accomplished appreciable and demonstrable favorable results.

Under all circumstances the cure of a guinea-pig offers as great difficulties as does the successful treatment of tuberculosis in man, and much will depend upon the good-will and painstaking efforts or otherwise of the experimenter as to what the final results shall be.

¹ Cent. f. Bakt. u. Parasit., 1895, xviii., Nos. 4, 5, p. 125.

The death of the animal, however, does not necessarily prove that no curative influence has been obtained, even if gross tubercular lesions are present. To show such an influence, or to show the contrary, requires most painstaking pathological and histological studies of the tubercular lesions which are found.

That the infections in the present experiments were highly virulent and severe, appears from the rapidly fatal course of the disease in the animals treated. With the use of an indifferent product of antiphthisin, administered every two or three days in increasing doses, the fatal result was probably an inevitable fact before any curative influence could be exerted, and the fatal results probably would only have been delayed, even if a product identical with my own had been applied in the same manner.

EDWIN KLEBS, M.D.

ASHEVILLE, N. C., December 30, 1895.

ANTIPHTHISIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The recently published paper of Dr. Trudeau on his experimental research with the view of eliciting the chemistry of the bacterial products in tuberculosis, and more particularly to show that "antiphthisin" is a diluted tuberculin which has no influence upon experimental tuberculosis, leads me to present my views on the subject, not as an expert chemist or bacteriologist, but as a practitioner who has seen much of the use of tuberculin in the treatment of human tuberculosis, and has also for some six months past applied "antiphthisin" with highly satisfactory results.

From a disinterested standpoint, it appears to me that it is as yet unexplained why Dr. Trudeau has not made sure that he really separated antiphthisin from the culture fluid, especially since he could have readily obtained more details from Professor Klebs himself, who is within easy reach of communication.

It is further unexplained why Dr. Trudeau did not apply to Professor Klebs for a specimen of antiphthisin as produced by him, and compare his product with that of Professor Klebs. As I understand it, the process of separation is an exceedingly difficult and delicate one, and each lot of antiphthisin is thoroughly tested upon the infected animal before it is finally accepted as perfect and given out for clinical use.

All who have followed the questions in the chemistry of albuminoids must be impressed with the great difficulties that here present themselves, when a similar substance, a bacterial product, is to be produced and isolated from other substances; and I have reason to know that in the laboratory where "antiphthisin" is now produced in this country, and where the equipment is with special reference to its production, under the immediate charge of Professor Klebs himself, it took from March last until the beginning of October before the first specimen was completed and given out to the profession.

In the animal experiments of Dr. Trudeau, the degree of infection is not shown; that it was a very severe and virulent one would appear from the early death of all the animals, and treatment of such animals every second or third day gave little opportunity for prevention of a fatal issue.

But whatever the results of the animal experiment might have been, they are irrelevant and not admissible for comparison with those obtained by Professor Klebs, simply because Dr. Trudeau did not employ the same product, but one manufactured by himself, which undoubtedly differed materially, if not entirely, from antiphthisin (Klebs).

If Dr. Trudeau did employ a weak solution of tu-

berculin, he failed to obtain the results which Koch produced with tuberculin, and which even Baumgarten had to admit as possible.

The death of the experiment animal is, however, still no proof in itself. The histological changes in the tubercle itself should have been studied and observed.

In conclusion, I refer to the satisfactory clinical results which have been obtained under the use of antiphthisin, as shown by Dennison, Von Ruck, Taylor, Kinney, myself, and others, proving its much greater safety as compared with tuberculin; and that toxic substances have been eliminated must be apparent from the simple fact that we can give doses of antiphthisin a hundred or more times greater than of tuberculin, whereas the amount of organic matter in the two preparations is about as four of tuberculin to one of antiphthisin.

C. P. AMBLER, M.D.

CANTON, OHIO.

STATISTICS OF TYPHUS-FEVER TREATMENT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the excellent paper on "The Clinical Aspect of the Typhoid-Fever Epidemic at Stamford, Conn.," which appeared in your issue of December 14th, there is much of interest to be noted. The most important statement, however, is the remarkable result of the treatment adopted. Fourteen cases recovered without any treatment whatever, and the others were treated on the expectant antiseptic plan, and by copious libations of water. Despite the severity of the epidemic, as indicated by the large number of hemorrhages, diarrhoeas, tympanites, and hypostatic pneumonias, the mortality was only 6.6 per cent. As this is the smallest mortality on record in a large number of cases reported from private practice not treated by the Brand baths, it would be of interest to the profession and inure to the great benefit of suffering humanity if the treatment were more thoroughly discussed. There is one error in Dr. Pierson's valuable paper, which I desire to point out, viz., the statement that the advocates of the cold-bath treatment claim a mortality of seven per cent. If this were correct, the Stamford treatment would surely deserve universal imitation, inasmuch as the Brand bath treatment is exacting, expensive, and unpleasant.

The Brand bath was introduced into practice in this country by a plea which I had the honor to make for it before the State Medical Society at Albany in February, 1889. Although some of our most eminent clinical teachers were present at that meeting, among them the lamented Loomis and Leaming, not a voice was raised in favor of it. The principal speaker condemned it because "he had seen and heard of several deaths having been produced by it." Being convinced of the life-saving value of this treatment, I have regarded it as a duty to advocate it whenever opportunity presented, with the following result: On my return from Albany Dr. Austin Flint requested me to instruct the house staff of his division in the technique of the Brand bath. It has since that time been practised successfully in this division, and it is now practised in the Roosevelt, New York, St. Luke's, Manhattan, Presbyterian, and in some of the divisions of Bellevue Hospitals; it is taught by Delafield and Peabody in New York, by Pepper and Wilson in Philadelphia, by Osler in Baltimore, and by others. Indeed, the Brand method has more able and earnest advocates in America than in any other part of the world, simply because American physicians are practical and willing to set aside prejudices when they are appealed to by convincing arguments.

Despite the success of my propaganda, I am ready

to abandon this method whenever a less troublesome, less unpleasant, and less expensive treatment should be demonstrated to bring as good or better results. In the interest of fairness, however, I beg to take issue with the author of the article referred to, and to challenge the inference that the best results claimed by the advocates of the bath treatment are seven per cent. The Stamford statistics, excellent and creditable as they are, do not approach the ideal results of the Brand bath method.

Dr. Brand has published 1,293 cases from the following sources: Juergensen (Tuebingen), 217 cases, 1 death; Vogl (Munich), 221 cases, 6 deaths; Military Hospital, Stralsund, 257 cases, 1 death; Military Hospital, Stettin, 186 cases, 3 deaths; Brand private practice, 342 cases, 1 death. Total, 1,223 cases, 12 deaths = 1 per cent.

None of the cases which died had received the bath before the fifth day. They all died from complications which Brand claims as preventable by beginning treatment before. Vogl, the Medical Director of the Munich Military Hospitals, has reported that in the first division, where the strict Brand method was used in 1880, 428 cases were treated, with a mortality of 2.7 per cent. Brand collates twenty-three separate reports from German and French private and hospital practice, consisting of 5,573 cases, with 234 deaths = 3.9 per cent. Dr. Bouveret reports from the Lyons Red Cross Hospital in 1891 100 cases, with a mortality of 3 per cent. In the German Hospital of Philadelphia there were 94 cases treated from February, 1890, to February, 1891, without a death, while the mortality in 271 cases in the other hospitals was 13.29 per cent. Dr. Carl Borning reports, in *The Physician and Surgeon* of December, 1889, sixty-one cases treated, without a death, by the Brand method. Without going into tedious detail, we have here reports from the most varied sources, with a mortality ranging from nothing to 3.9 per cent.

In the light of these excellent and indubitable results, it is not surprising that so acute an observer and so conservative a practitioner as Prof. Wm. Osler, of Johns Hopkins University, last summer told the British Medical Association, in which the cruelty of the Brand method had been brought forward as an objection, that his personal experience has convinced him of its value; and that no matter how cruel the bath treatment may seem, he would continue to use it, because it saves many lives.

In conclusion, permit me to call attention to the importance of following the exact technique laid down by Brand as nearly as possible, and the unfairness of charging failures due to deviations, when the ideal method was not executed. So common is the error of confounding the latter with all sorts of cold bathing that in your issue of December 30, 1893, I was criticised for presuming to claim priority of introducing the Brand bath in typhoid fever in this country, your correspondent claiming in a subsequent letter to me that he had been taught cold bathing in fever twenty years previously by Dr. Loomis, and had been examined upon it on his entrance as an interne to Charity Hospital. And yet Dr. Loomis said, in a discussion on the Brand method, reported in the *MEDICAL RECORD* of March 22, 1890: "If an opportunity occurred to him he would be glad to give the method a thorough trial." Dr. Delafield said, on the same occasion, that "he had no real experience with the Brand method of bathing." That the latter gentleman is now an earnest advocate of this bath is evident from his lectures and his practice. Let me not be understood as casting the slightest criticism upon the Stamford treatment. Its results are simply marvellous. My chief object is to elicit more detailed information by case histories and other details on the exact methods pursued. I desire also

to call attention to the error of charging the strict Brand method with a mortality of seven per cent., and to the fact that failures resulting from all sorts of cold bathing are not chargeable to the Brand method, which has a special technique and rationale. The latter should be thoroughly mastered (as they are taught by Delafield in the Roosevelt Hospital) before practising the method.

SIMON BARUCH, M.D.

51 WEST SEVENTEETH STREET.

Medical Items.

Cost of Water in Milk.—It is stated that in New Orleans about \$1,000,000 is annually spent for milk. Since one-third of this is composed of water from the mains, the citizens of New Orleans are paying over \$300,000 per annum for the water which is in their milk.

Questionable Modesty.—*Anxious Parent* (exultingly) to *Consultant*—It was you who did it. I knew when we asked for you we would be safe.

Wily Consultant (modestly)—Well, we all do the best we can. Your doctor is a very good man. To tell the truth I was surprised to find that he understood the case so well. You say he changed the treatment at once. Well, I might have been mistaken myself. It's wonderful to see what little things will do.

Experimental Polydactylism.—Dr. Giard (*Soc. de Biologie*, December 7, 1895) has experimentally produced supernumerary toes on a Spanish salamander by placing it in a glass globe half filled with water. In attempts to keep the head above water the toes are gradually worn away. If now aquatic plants are placed in the globe upon which the feet can rest, so that effort is no longer required, and an abundance of food is given, the toes regenerate with surprising rapidity and degree. In one case where there were previously but four toes on the front feet, six developed and one of the hind toes became bifid.

The Hanbury Medal.—The Pharmaceutical Society of Great Britain has presented the Hanbury medal to Dr. August Vogl, the professor of pharmacology. This is the eighth award of this medal, which was presented in 1881 to Flückiger, in 1883 to John Elliot Howard, in 1885 to Dragendorff, in 1887 to Dymok, in 1889 to Plaichon, in 1891 to Hesse, and in 1893 to Maish.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

SOME OF THE USES OF ELECTROLYSIS IN DERMATOLOGY.

By CHARLES W. ALLEN, M.D.,

NEW YORK,

LATE SURGEON TO THE CITY HOSPITAL, AND DERMATOLOGIST TO THE RANDALL'S ISLAND HOSPITALS.

THE title which I have selected to cover the subject of our discussion to-night implies, as I have intended it should, that electrolysis has a varied application in the treatment of skin affections. It is not alone in hypertrichosis, or unusual growths of hair in unusual and undesirable locations, that the electrolytic needle finds its sphere of greatest usefulness. Since Hardaway of St. Louis first introduced the procedure for this purpose some seventeen years ago, dermatologists in this country, and, to a lesser degree in Europe with the exception perhaps of France, have recognized its greater possibilities and have extended its use to the removal of smaller tumors, naevi, and to the cure of a number of abnormal conditions of the skin of which we shall speak further on. Presuming that you are all familiar with the general details of the operation for removing superfluous hair, I shall confine myself more particularly to the practical points which my experience has taught me are important.

I. What can we Promise an Applicant for Relief from a Disfiguring Growth of Hair?—I usually advise patients to have hairs, abnormal growths, and blemishes removed from the face whenever they are a source of worry and annoyance, as they so often are to women and at times also to men. I believe it the duty of all to make themselves as attractive as possible and to avail themselves of such cosmetic procedures as will add to the general æsthetic effect of existence. Conversely I believe it a sin for any one to go through life with a facial defect which can be readily corrected, and while chafing under its presence, answer suggestions as to its correction with such remarks as "I was born with it and might as well die with it," or "if the Lord didn't want me to have it he wouldn't have put it there." Women, and men too, should show honor to their Creator by making themselves appear as like as possible to their ideal of His image, whenever it is reasonably feasible. Occasionally application is made for the removal of a fine silky and not at all disfiguring growth upon the lip. I have upon several occasions advised against the needle in such cases, as well as in the case of single moles so situated that they are rather to be regarded as beauty-marks than otherwise. The first rule of surgery—to do no harm—must here apply, and the production of a cicatrix more distasteful than the original trouble must be guarded against. Once having decided that the case is suitable for operation, the patient must be made to understand that many sittings will be required until all hairs are permanently removed. It is well, too, that the fee for each *séance* or for the work

as a whole should be agreed upon beforehand. This will best impress upon the patient the difficulties of the task and may prevent dissatisfaction at what might appear a slow progress. I endeavor to inform my patients beforehand that a certain proportion of hairs removed will grow again and that the operation is to be repeated until the gradually diminishing proportion of "reproduction hairs," as I call them, is *nil*.

To illustrate: Miss W— came to me from Connecticut in March, 1894, and in several sittings extending over a week's time I removed three hundred and fifty-seven long coarse hairs from the upper lip and chin, destroying at the same time a small vascular naevus upon the cheek. I told the lady that within some months certain of these hairs removed, in which the point of the needle had not exactly touched the hair papilla, would grow again and that it was to be expected in the natural course of events that a certain number of other hairs now present, but fine and devoid of pigment, would grow larger, coarser, and darker. I was not therefore surprised to see the lady again in January of this year, nor was she surprised at the necessity for her return to me.

I now found 57 hairs requiring removal from the upper lip, 27 from the left side of the chin, 16 from the right side, and 55 from all other portions of the face, making a total of 155, or over 200 less than eight months previously. I have not seen the patient since, but no doubt there are now present fifty or more thick hairs requiring some attention. Turning to another case for a supplementary history of the way these cases run: Miss L— came to me on May 5, 1894, and within a week I removed over 400 long coarse hairs from the chin and neck. In October of the same year 150 required removal. In December, 100. In March, 1895, 100 were again removed. In May there were but 46 to operate upon, and now in this very month I have removed 40 long hairs, nine-tenths of which I venture to say were not "reproduction hairs" but hairs which were less developed and not touched in previous operations.

I say this for the reason that they were almost all quite superficially implanted in the skin, when drawn upon, causing a slight elevation of the peri-pilary tissues and leaving on extraction a dell rather than a tubular follicle. They were also less coarse and less deeply pigmented than the original growth.

This brings up the question—

2. Does Electrolysis Tend to Stimulate the Growth of Neighboring Hairs?—I have believed and do believe that to a limited extent the irritation of the surrounding tissues caused by the current and the succeeding erythema favor increased activity in the growth of near-by hairs which are at first ignored. It is partly for this reason that I advise against operating upon the upper lip near the corner of the mouth unless most of the fine hairs are at the same time destroyed. I say partly, because for some reason the reactionary irritation is very apt to be pronounced in this region and may result in small white, perhaps pitted scars of tell-tale nature.

I wish to be thoroughly understood upon this point of electrolysis as a stimulant to new growth of hair. If it would do what many patients and some physicians

¹ Paper read before the Lenox Medical Society, Dec. 9, 1895.

seem to think it capable of, the needle would prove one of the very best means of treating bald heads. It will, in my opinion, not cause new hairs to grow, but I have thought at times that the finer and lanugo hairs already present about the larger hairs operated upon became more rapidly developed after several applications of the method, and in course of time required themselves the needle sooner than they otherwise would.

3. **Battery, Electrodes, etc.**, are largely a matter of choice and expediency. Any good galvanic battery will answer. The positive sponge-covered electrode may be employed, or a copper plate covered freshly for each patient with absorbent cotton wet in salt solution makes a cleanly and simple electrode for the patient to hold in the hand. For the negative, some prefer needles made from iridium, platinum, and even gold, to the ordinary steel needle or more blunted jeweler's broach which has been annealed to destroy its brittleness. The advantage of the soft metal electrodes is more theoretical than real it has always seemed to me, and I have been satisfied to use the broach which is delicate, pliable, and accommodates itself somewhat to the follicular canal, or even an ordinary cambric needle.

No needle will take the proper direction unless it is intelligently guided, and the knack of getting to the bottom of the follicle and no farther is one which comes with practice.

The needle-holder which I prefer is light, slender, and from four to five inches in length, without any button for making or breaking the current. In *nævus* operations upon children, the latter device is useful, enabling the operator to apply his positive sponge-covered electrode to some surface continuously, while in the adult it is preferable to have the current made and broken by the patient while the needle is in place.

In almost all writings upon the subject you will find the instruction given to insert the needle alongside of the hair shaft until the bulb is reached (or you think you have reached it), and after the current has passed for a certain length of time, say from five to twenty seconds, the operator being governed by the amount of frothy bubbling about the follicular opening, the needle is to be withdrawn and gentle traction made upon the hair with tweezers or forceps, when, if sufficient electrolytic action has taken place, the hair comes out readily and the chances of success are good; while, if it does not, the needle is to be reinserted. My own plan, which I think better than this, is to grasp the hair firmly with dressing-forceps and make slight traction. Close observation, perhaps with the aid of strong glasses which I sometimes use, enables one to judge at times of the angle of insertion of the root, and whether the particular hair is superficially or deeply implanted. The needle is then inserted alongside the shaft until a point is reached where the sensation is conveyed through the holder that the point has reached some obstruction. Possibly the hair may be drawn in again if pressure be further exerted. The circuit is now made by the patient touching the tips of the fingers to the positive electrode at the signal "on." If the point of the needle is favorably located at the bottom of the follicle or pierces the root, the hair almost at once comes away in the grasp of the forceps. The needle is not withdrawn at once, however, but remains inserted and perhaps is moved about so as to occupy the whole of the canal left by the extracted hair, for a few seconds longer. The circuit is now broken by the removal of the fingers at the signal "off" and the needle is painlessly withdrawn.

The use of a galvanometer and rheostat interposed in the circuit is a desideratum but not an absolute

necessity, as many writers have claimed. Sometimes I measure the current accurately and more often I am governed by the patient's sensations, the amount of local reaction, and my own judgment based upon experience as to the number of cells to employ. Recently I have been using a bichloride of silver dry-cell battery of high electromotive force. Here a galvanometer is a *sine qua non*. Usually from half a milliamperere up to three milliamperes are required, or when working without a galvanometer from four to ten cells of a constant-current battery. The intensity of the current must needs vary with the patient's susceptibility, the atmospheric conditions, and the practical results observed; the desideratum being to get along with the least current strength which will do the work.

For beginners, and perhaps for the first sittings with new patients, a galvanometer is advisable.

4. **Who should Practise Electrolysis for Hair Destruction?**—The question has been raised whether it is consistent with professional dignity and strictly within the province of the physician to do this kind of work.

If the female beard is to be destroyed there is only one method now known in my opinion which will do it effectively, viz., electrolysis, and there is only one class of people who should practise it, viz., the physicians. I have had many applications from young women who wished to be taught how to operate, but my invariable reply has been that no one but a physician should attempt it, and if I could make laws I would make one to that effect. The electrolysis of the bathing establishment, of the advertising dermatologist, and of quacks in general who know more about extracting money from their victims than they do about extracting hairs, has done much to cast odium upon a most useful method. Any painstaking physician can readily acquire the requisite skill, and then all that is needed is patience, care, and good judgment.

The man who becomes so enthusiastic in the presence of a bearded lady that he will work seven hours on a stretch—as one writer reports that he has done—will most probably fail to give lasting satisfaction. It is inconsistent with really good work to devote more than an hour at a time to a case, removing about fifty or sixty hairs. The work is trying, and the operator is ready to stop before the patient wearies. The only objection I see to the general practitioner engaging in this work if he wishes, is the time required for each case after he has taken time to become adept.

5. **Electrolyzation of Nævi.**—Several varieties of *nævi* are removed with greater facility and satisfaction by the electric needle than by other methods. Thus the small *nævus araneus*, deriving its name from the spider-leg-like appearance of its off-shoots, is destroyed sometimes at one sitting by puncturing its central portion and passing for a few seconds a current sufficiently strong to decompose the contained blood and bleach the whole area involved. Telangiectases which occur later in life, and *nævi* of limited extent are removed with equal ease, while quite extensive superficial port-wine mark or *nævus vinosus* may with time and persistency on the part of both patient and physician result in a very satisfactory condition, as I was able to demonstrate in a case shown at one of the Dermatological Society meetings last winter, where such a disfiguring mark upon the side of a lady's neck had been almost wholly removed. Here I found that very superficial prickings with a sharp needle, while painful, gave better results than deeper insertion of the point and longer passage of the current. Nothing succeeds better than electricity in *nævus pilosus*, especially those bearing a few stiff, deep-rooted hairs. These I destroy first, making use for this purpose of a greater current strength than in

ordinary hirsuties. The hairs being thus removed, sometimes very little in addition is required. If, however, the mole is large, I use a flat-bladed sharp-edged needle, passing it through the base of the growth at the skin *niveau* just as I do in *nævus papillomatosis*, *nævus lipomatodes*, and warty growths in general.

My method here differs from those hitherto advised. The usual instruction is to pass the needle through the growth in various directions, and when sufficient effect has been produced to allow it to shrink up and fall off in the course of a few weeks.

This delay in final results led me to employ the flat-bladed needle which I show you. Passed through the entire base of a small growth or through a segment of a large one, the apex being grasped by a mouse-tooth forceps, it is slowly but firmly moved, perhaps with a sawing motion, first through one side and then through the other. This leaves a skin-level surface, usually bloodless, and in many instances is alone sufficient to effect permanent cure. If, however, the growth appears to penetrate much beneath the skin, or if there is left a central bleeding point, or if the margins are not quite levelled off, the point of the needle can be used to puncture and thus destroy the necessary amount of tissue. The less done in this way, however, the less chance there is of any subsequent scarring.

Nævus vascularis is usually very difficult to cure in this way, and it is for this reason that I show you paintings of a case of

Vascular Nævus of the Vulva Cured by Electrolysis.—In November, 1893, Dr. Henry Koplik sent me a girl baby seven weeks of age who presented an ulcerating *nævus* occupying the lower half of the right *labium majus*. Under appropriate treatment the ulcer was allowed to heal after it had destroyed all of the vascular tumor it seemed capable of doing, viz., about one-half.

There was left around a central cicatrix a double circle of dilated vessels, and upon the inner side, extending into the vagina, was a portion of the original growth to which the ulceration had not extended. Beneath the cicatrix could be felt a vascular mass implicating the whole thickness of the skin and subcutaneous tissues of the region.

On December 11th I began treatment by electrolysis, first numbing the parts with chloride of ethyl spray and employing from eight to ten cells of a thirty-cell galvanic battery. I believe it was during this same month that I presented the child at the New York Dermatological Society (232d meeting).

Although some improvement had already taken place, the general consensus of opinion was that the case could not be cured by electrolysis. I will quote from the record of the proceeding the views of the gentlemen who spoke, to show you how the case was then regarded.

Dr. Fordyce advised puncturing with fine-pointed galvano-cautery wire.

Drs. Elliot and Sherwell stated that cavernous *nævi* were not materially affected by electrolysis, on account of the large size of the vessels. The thermo-cautery would be necessary to destroy them.

Dr. Jackson said electrolysis would cure a cavernous *nævus* only over bony prominences, not in soft tissue like the lip or vulva.

Dr. Taylor had seen a large *nævus* of the vulva cured by means of a shoemaker's awl heated to a white heat.

Dr. Lustgarten said that while it is quite possible that such a lesion as this could be cured by electrolysis, which is a method of cauterization, he thought it better, for cosmetic reasons, to refer such cases to the surgeon for operative interference.

Dr. Allen said that in this case the *nævus* extended

into the vagina and an operation might give rise to permanent narrowing of the ostium *vaginæ*. He said that ten years ago he had cured a cavernous *nævus* extending to both surfaces of the lip by means of electrolysis.

Dr. Taylor said he did not think the excision of the *nævus* in Dr. Allen's case would cause much involvement of the vagina.

I persisted in my treatment in spite of these views and used no other means of cure. I operated on January 2d and 7th, February 20th and 27th, April 14th, May 15th, July 13th, and October 5th and 19, 1894. Since then I have not seen the case. When I discharged the mother I told her the baby was practically well. Dr. Koplik has stated to me during the present month that he has within a few months examined the child and considers it cured. There are a few superficial red points, he tells me, but no tumor-mass of vessels to be felt more deeply. Such a vascular tumor in this situation might, in the event of pregnancy, put the patient's life in jeopardy if perchance the patient had not refused matrimony, considering the growth an impediment. I believe the needle did better for this patient than the knife would have done.

On July 23d of this year Dr. S. J. O'Neil sent me a lady who had upon the cheek just below the right eye a papillomatous pigmented and hairy mole one and a half centimetres in diameter. I operated upon it with the flat needle, removing sections by the electrolytic cut at several sittings and present the patient to-night that you may judge of the result. The scar is still somewhat red at times and slightly uneven, but is much less noticeable than would be a scar after excision with the knife. I have employed electrolysis in elephantiasis, lupus, keloid, acne rosacea, milium, and a variety of other conditions which I cannot presume upon your patience to discuss at this time. I would say I believe it will prove the very best method of treating xanthelasma of the eyelids. I have been much pleased with the needle as a means of obliterating dilated sebaceous follicles and crypts. In obstinate comedones a three-angled or glover's needle passed well into follicular canals may often arrest the re-formation of the plug. Upon the nose I have entirely closed up in this way dilated and very annoying follicular openings. During the past month a man presented himself at the office with a swelling on either side of the *frænum glandis* giving the appearance of abnormal fulness to this portion of the organ. Palpation disclosed a rather firm mass somewhat movable and about the size of a white bean upon either side. Diagnosis: Hardened, perhaps calcareous, sebaceous material in dilated sebaceous crypts or follicles of Tyson. Through the rather small follicular opening, first on one side, then on the other, a very slender knife blade was passed and the concretion, which had the consistence of rather old putty, was broken up and removed piecemeal. By pinching up the tissues and pressing toward the external opening the last vestige of the crypt's contents was removed. I then passed a medium-sized needle into the openings and with about three milliamperes' current strength swept the point over the whole inner surface. Following this for a few days there was a little inflammation and slight discharge. Examination within a few days past shows an apparent obliteration not only of the duct but of the cystic cavity as well. The advantage of the needle in such cases is that it acts through an opening which is too small to permit of easy introduction of any usual caustic. Fluids will not penetrate readily, but much the same effect can be obtained from the needle as from peroxide of hydrogen followed by a chemical cautery.

I will speak of only one thing more—freckles. In spite of the many vaunted freckle lotions these an-

noying pigmentary deposits are difficult of removal. Where a few dark ones of good size are scattered over the face they can be removed with the needle in one of two ways: either by pricking lightly over their surface with a weak current, or with half a milliamperé undermining the epidermis with a fine needle or a very narrow-bladed flat one until the surface above the needle is distinctly blanched. The epidermis exfoliates within a few days and with it the pigment which is contained in the rete mucosum.

In conclusion, gentlemen, I will only say that I cannot quite agree with my distinguished friend, Dr. J. C. White of Boston, who said at the last meeting of the American Dermatological Association that little seemed to be known to-day about the possibilities and limits of electrolysis that was not known when Hardaway first introduced it in dermatology. I think that each one of the few who have written upon the subject, out of the comparatively large number of those who have employed the method, has added his mite and that the aggregate of knowledge makes electrolysis to-day something much more valuable and possessed of greater capabilities than ever the originator Dr. Michel or the promoter Dr. Hardaway thought it would have.

126 EAST SIXTIETH STREET.

EXCISION OF THE KNEE AS AN ORTHOPÆDIC PROCEDURE.

By W. O. PLIMPTON, M.D.,

INSTRUCTOR IN ORTHOPÆDIC SURGERY IN UNIVERSITY OF THE CITY OF NEW YORK, MEDICAL DEPARTMENT; INSTRUCTOR IN ORTHOPÆDIC SURGERY IN NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL.

I ASSUME, in the presentation of this paper, that excision of the knee comes within the scope of the orthopædic surgeon's domain of treatment, that it has its own place as well as mechanics in dealing with pathological conditions of the knee, and that the surgeon should have recourse to it under proper limitations to stay the ravages of disease, and save for his patient a useful limb. The success of the operation is no longer an experiment, when performed under right conditions and by a skilful operator, and should not only save limbs but lives. The when and how of the operation are matters of discussion, points upon which general surgeons differ, and again the orthopædic and general surgeons take issue. Extreme individual views are entertained by both. This can be only too evident, when a distinguished Edinburgh surgeon tells us that all cases, whether of synovial disease alone or those in which the bone is involved as well, should be excised. And, on the other hand, the orthopædic surgeon, who would carry mechanical treatment to the verge of amputation, is treading upon extreme territory. Excision of the knee should occupy the position of a "golden mean," to be resorted to where mechanical treatment has not availed and cannot do so, and before amputation is a necessity. That a stiff leg is to be preferred to an artificial limb is a generally recognized fact, and amputation is a last resort greatly to be deplored.

Too much cannot be said in favor of early treatment by mechanical and fixation methods in disease of the knee-joint. And I would emphasize strongly that if the profession at large should recognize disease of this joint in its incipency, and would employ or have employed extension and fixation methods of treatment, comparatively few cases would get so far as to necessitate excision. It is the duty of every orthopædic surgeon who teaches, either in the under-graduate or post-graduate schools, to lay special stress upon early recognition, as well as early mechanical treatment, of these diseases. But, alas! the old diagnostic song of rheu-

matism, strain, or struma, with its treatment refrain of iodine, blister, poultice, and wait, is still sung by many a general practitioner and surgeon. The result is, that long after the disease has passed its incipency, the patient is referred, or applies himself, to the orthopædic surgeon for treatment.

A condition of disease more or less advanced presents itself, involving different structures, with deformity more or less pronounced. The skill and experience of the specialist must strike the balance, and determine what line of treatment is best pursued. Where abscesses and sinuses are not present, the immobilization and extension plan should at least be thoroughly tried. A large proportion of cases will yield to this method, and show immediate improvement, with prospects of ultimate recovery.

Since antiseptic methods of operation have so diminished the risks to life and limb, we are justified in interfering in an operative way much earlier than was formerly deemed judicious. Exploratory incisions are in many instances to be recommended. They many times furnish the surgeon with much valuable information respecting the extent of the disease. A finger introduced into a joint with antiseptic precautions will tell the facts, which otherwise would be recognized too late to save limb or life. It is then easy to say what operative procedure is necessary. I think, as a rule, more disease is found than was suspected.

When the fixation and extension plan of treatment has been conscientiously tried, and has not arrested the disease, which is manifestly on the increase, we should explore the joint, and do whatever the conditions demand, whether to wash out or excise. When the articular surfaces are destroyed, the bone and the soft parts extensively involved, the joints should be excised (except, perhaps, in young children, which exception I will mention later). If, however, only the synovial membrane and soft parts are infiltrated, and the joint filled with fluid and cheesy material, it should be washed out with some of the various solutions recommended by Schede, Koenig, and the late Professor Volkmann, of Germany.

The washing may be accomplished by a trocar and cannula, first emptying the joint of its fluid contents, then flushing out the parts through the cannula with whatever solution is desired. An incision into the joint large enough to admit the finger is to be preferred, since by this procedure we can, through the opening, investigate the extent of the disease, and the flocculent material inside, if there be any, which would not pass through a cannula can be evacuated. In Dr. A. M. Phelps' clinic, with which I am connected, at the New York Post-Graduate Medical School and Hospital, the irrigation used is a considerable quantity of a 1 to 2,000 bichloride solution, with much kneading and manipulation of parts to bring the solution in contact with the entire joint surface. The 1 to 2,000 should be followed by a 1 to 5,000 bichloride solution. The incision is then closed, by first stitching up the capsule closely, and then the outside parts with another line of sutures. The fixation plan may now be continued as before. The result is, as a rule, satisfactory.

The question of how long mechanical treatment should be continued before resorting to operation is still open to discussion. I would say a few weeks or months were long enough to determine if the disease is being arrested. The only valid argument in favor of treatment extending over years in many cases with a severe type of disease, is the hope or possibility of a useful and movable joint, with little or no shortening. But when we see ankylosis result in cases long treated, with the accompanying discomfort or pain during a part or all of that time, with the system exposed to further infection, and others whose joints have been excised walking about with a useful limb and absence

of pain, having been treated perhaps only as many months as the first has years; we stop to consider.

Comparing modern statistics in excision of the knee in the hands of good operators, so far as mortality and

In looking up opinions as to how advanced in age patients may be to bear the operation of excision well, I find it is generally conceded that the danger to life increases in rapid ratio after fifty, although often operations are successful much later. Statistics place the most favorable time early in life.

I must not fail to mention reproduction of tissue through the medium of blood-clot, and its importance in the consideration of surgical treatment of the knee. Since antiseptic methods have made it possible to utilize this most important principle in the reproduction of new tissue, many limbs have been saved which were formerly doomed to amputation, because of the great destruction of bone. It saves the bone in length where many and extensive foci of disease appear in the head, even where it extends into the shaft, by filling in the spaces and later becoming replaced by bone tissue. It is not necessary to cut repeated sections from the articular end until no diseased foci can be found, but with a sharp scoop cut them out, allowing them to fill with blood, leaving the healthy bone as the framework from which the new cells may find their way into the clot, thus transforming it into solid bone.

In the series of excisions upon which I shall report, there are several examples of great destruction from osteomyelitis and tuberculous disease, in which amputation was avoided and several inches saved to the length of the limb, by allowing the cavity to fill with blood, through which new tissue was formed. In one case of osteomyelitis as much as seven inches of bone was re-

FIG. 1. First Incision.

useful limbs go, when as good a showing can be made (in these two particulars) as in a series of sixty-five excisions of the knee, upon which I shall presently report, we are led to ask why the operation is not done more frequently. Statistics prove, that when joints are doing badly, operative treatment combined with mechanical gives the best results.

In addition to the class already mentioned as suitable for excision are the following: Relapsing cases of long standing; abscess cases with or without sinuses, whether containing tuberculous or pyogenic infection (with extensive involvement of bone and infiltration of soft parts); cases of osteomyelitis involving the joint; knees with ankylosis in the faulty positions of flexion, luxation or subluxation, or old arthritic cases, with but little bone disease, which do not yield to mechanical treatment. There is still another class in which excision is the only alternative, namely, in those patients who live in a locality where expert orthopaedic attendance cannot be had. Also in the case of the laboring man, who has no means of support while undergoing a prolonged period of treatment. Even though the disease be slight, their circumstances make the operation a necessity. Excision of the knee should not be practised in children under eight, and, preferably, twelve years of age. Cutting at the epiphysis at that time of life greatly interferes with the growth of the limb. Relapses as regards flexion frequently occur. Excision should be performed in these young cases only where the disease is so extensive that no other operation would avail. Arthrorectomy or other scraping operation is to be recommended.

All abscesses of joints, whether in children or adults, should be opened and thoroughly drained, sinuses should be laid open, and the necrosed bone cut away by scoop, chisel, or gouge. Drainage through the joint in young patients with abscesses should, if needed, be kept up as long as the disease is active. Fixation should also be continued at the same time.

FIG. 2. Flap Turned.

produced. In determining what operation for excision of the knee best subserves the requirements, it may be said that the method which allows the most complete removal of all diseased tissue, and gives perfect

drainage, retains the parts in best apposition, and fixes the bones without the use of pins or wire, and last, but not least, the one that can be done with the greatest ease and rapidity, is to be preferred. Without entering into a discussion of the merits and demerits of the operations devised and performed by different surgeons, I believe that Fenwick's section of the bone (see Fig. 5), with Phelps' method of removing diseased soft parts together with bone as described below, fulfils all the requirements mentioned above, with a few exceptions. Where the head of the femur is destroyed, precluding the section according to Fenwick, Dr. Phelps has devised a method to meet this condition by sawing a wedge shape at the end of the femur and a V in the tibia for its reception. The essential feature in Fenwick's operation is the sawing of the bone in a line parallel to the articular surfaces, so that when placed in apposition the convex surface of the femur fits the concavity in the head of the tibia. The bones are so locked that there is little or no chance of their slipping and no tendency to rotate outward in the dressing. No pins or wires are needed to keep the bones in contact. This is greatly in the patient's favor, since the necessary period of anaesthesia is shortened by ten or fifteen minutes. Where wire and pins are used, they not infrequently give trouble later.

The length of time taken for excision of the knee has an important lesson for us in the statistics respecting the mortality of the operation. Mr. A. G. Miller, of Edinburgh, in a report on excision, advised against it in certain feeble patients (otherwise suitable cases), recommending amputation because it could be done in a much shorter time, remarking that while in either operation the shock was about the same, the effect of the longer period of anaesthesia was to lessen greatly the patient's chance of life. There is a vast difference in the ether shock, whether your patient is under its influence twenty minutes or two hours. This point is clearly set forth and proven in a series of clinical lectures by Dr. William H. Porter on anaesthesia, delivered before the class of the New York Post-Graduate Medical School and Hospital.

The shock of the operation in excision of the knee must of necessity be profound. Add to this the shock produced by ether in an operation lasting from one to two hours instead of

FIG. 4.—Articular Surfaces Exposed.

twenty minutes, and the chance of saving the patient's life is greatly reduced. Except in extreme cases no surgeon, after he is familiar with the operation here recommended, ought to take more than fifteen to twenty minutes to operate and apply the dressing. If the steps of the operation, which I will recount, are followed, I think you will be convinced that it can be performed within the time specified.

Entering the knife a little posterior to and above one of the condyles of the femur, a curved incision is made, extending sufficiently below the patella to expose the margin of the head of the tibia, terminating at a corresponding point on the opposite condyle (see Fig. 1). This incision opens the joint more extensively than any other. Dissect the flap well up, as in Fig. 2. A curved incision above the patella removes nearly the entire synovial sac, together with the patella (see Fig. 3). Instead of picking at the diseased parts with forceps and scissors before going further, thus consuming valuable time, with consequent danger to the patient, the lateral and crucial ligaments are divided and the knee is flexed, as in Fig. 4. With a saw proceed at once to resect the bones, at the same time sawing out a large portion of the diseased soft spots, as well as bone (see Fig. 5). This done, the entire joint is removed, with nearly all of the disease. With scissors and a Volkmann's spoon, the remaining disease is quickly cleared away. This concludes the cutting part of the operation. Ligate the three or four arteries if necessary. A continuous suture closes the incision, drainage at the same time being introduced (see Fig. 6). The dressing is the usual gauze and cotton, with plaster-of-Paris extending from the toes to the

FIG. 3.—The Patella and Capsule of Joint Removed

groin. It is due more to the method than to the skill of the surgeon that the operation is so quickly performed.

In children under twelve years of age, it is best to resect the hamstrings to prevent subsequent flexion.

FIG. 5.—Bone Resected.

Dress the limb in a perfectly straight position, else flexion may result later. The limb should be swung up at an angle of about forty degrees. The patient should not walk on the limb without support until after there is solid union. Some form of support, either plaster-of-Paris or a brace, should be continued from three months to one or more years, depending on the age of the patient and condition of the limb. The younger the patient the longer the support should be worn to prevent flexion.

It is hardly reliable to quote statistics made before the employment of antiseptics, respecting the mortality of this operation. Quoting from Dr. Phelps' paper of 1888, reports of 329 operations by different operators give a mortality of 3.03 per cent. In this table I find Fenwick gives one of the best records, viz., 1 death in 28. Miller gives the following statistics: In 30 excisions of the knee, performed in the Royal Infirmary, Edinburgh,¹ 1 death occurred; 13 knees were excised for synovial disease alone, the bone not being involved; 18 good and useful limbs resulted; 3 had fairly useful limbs; 5 had to be amputated.

Barker, at the University College, London (January, 1893), reports 25 operations on the knee-joint, without a death, but all but 4 were arthrectomies. Only 4 were excised, one of these being under twenty-one years of age. He is inclined to think, in speaking of the limit of age being a contraindication for excision, that if antiseptic methods are carried out, the time of life is not to be considered more seriously than in other operations of similar magnitude.

Mr. H. G. Hows, from Guy's Hospital, London, reports 130 cases of excision: Four deaths were due to operation, or a trifle over three per cent. mortality; fifty per cent. had satisfactory limbs; 8 had shortening over two inches; 7 short from sequestra; most of the remaining had less than one inch of shortening; 21 lost sight of; 12 cases, ages three to twelve years, became much flexed; 10 others slightly flexed; 26 were amputated within three years, for suppurating sinuses and necrosed bone; 2 for other causes; 5 died from the amputation.

I have obtained, from the history books of the New York Post-Graduate Medical School and Hospital, from the City Hospital, and Mary Fletcher Hospital, University of Vermont, Burlington, together with ten from private case books, the records of 65 excisions of the knee, performed by Dr. Phelps. I shall summarize results. No deaths occurred from the

operation itself; one patient died from excessive administration of ether while on the table; one died three months after the operation, from sarcoma appearing in knee after it was entirely healed. A large number of these cases were most unfavorable for excision, inasmuch as the disease was very extensive, multiple sinuses occurring in soft parts, with bones honeycombed with tuberculous disease or osteomyelitis. Nearly all had at some time been faithfully treated by mechanics. On most of these Fenwick's operation was performed; Phelps' method was employed in a number.

No wiring or pinning of bones was done except in the first cases. No amputations have occurred in this series. All resulted in bony ankylosis, in four months to one year, except one from the Post-Graduate, recently operated upon, in which sufficient time has not elapsed for such union.

Bony union should be considered a perfect result in excision. One re-excision appears. In one imperfect case a painful scar occurred, which scar tissue was later removed; subsequently the leg was fractured in a railroad accident, and case lost sight of.

Operation in only 6 cases was followed by pus. In

FIG. 6.—Wound Closed.

this series the average age was 20.67 years; youngest, 7 years; oldest, 53 years.

Average shortening in 57 cases, 0.88 inch; least shortening, $\frac{1}{2}$ inch; greatest shortening, 3 inches.

Average time in hospital, 7.7 weeks.

Form of bone section employed: Not mentioned,

¹ Lancet, Feb. 3, 1893.

3; Volkman's,¹ 1; Neuber's,² 3; Phelps',³ 8; Fenwick's,⁴ 50.

The average time of operation in the last half of this series will not exceed fourteen and one-half minutes, save in an exceptionally bad case. During the last five years I have assisted Dr. Phelps in nearly, if not quite, all of his excisions performed at the New York Post-Graduate Medical School and Hospital. The watch has been held repeatedly by members of the class of matriculates present, and the time of operation including dressings has oftener been less than more than fourteen and one-half minutes. At the last operation in which I assisted, the watches of several were held. It was just ten minutes from the time the first incision was made until the last plaster bandage was in place. The last case mentioned left the hospital in six weeks from the day of operation, with all parts healed. That no mortality due to the operation has occurred in this series of sixty-five cases, I believe, is attributable in a great measure to the fact that the patients were under ether but a very few minutes, hence having very little ether shock added to that of the operation.

THE PREVENTIVE TREATMENT OF SEASICKNESS.⁵

By A. D. ROCKWELL, M.D.,
NEW YORK.

THE literature of seasickness relating both to pathology and treatment is so extensive and so comprehensive that there is, I apprehend, nothing new to be said upon the subject. I at least know of nothing and shall attempt nothing in this direction. And yet, notwithstanding the many statements as to the nature and treatment of seasickness, there yet prevails, both on the part of the profession and the laity, a tendency to ignore the whole subject. The reasons for this neglect seem to me to be these:

1st. The disease, dreadful as it is, has come to be something of a byword. Suffer as a man may, his friends who do not suffer seem to see a humorous side to it. To speak of seasickness excites a smile. The occasion seems to be one for a joke rather than for sympathy, and then the fallacious idea very generally prevails that to be seasick is good for one, that it has a special power to relieve and clear up the system, and, therefore, even among those who fully appreciate the suffering it entails, a do-nothing policy is advocated.

2d. Another reason for this neglect is because of the very general disbelief in the efficacy of any remedy either to greatly relieve or to prevent seasickness. This disbelief, strange to say, is shared by every surgeon of an ocean steamer with whom I have conversed upon the subject, but great as is their experience along this line, I cannot but believe that it is far less satisfactory and valuable than that of some others who see a far less number of seasick persons. He fails to cure his seasick patients for the reason that, after nausea has once set in, the general experience has been that it is impossible to cure it. Nature must then take its course. In saying this, I do not forget the claims made by Dr. Winslow Warner Skinner

some years ago, in an elaborate series of papers on "Naupathia,"¹ in which he advanced the theory that seasickness was caused by a "general lowering of the arterial pressure, dependent upon paresis of the cardio-accelerator and vaso-constrictor nerve-centres, and that the cause of this paresis is a reflex inhibitory influence exerted upon these centres, originating either in the sensorium or in organs unequally and alternately pressed and pulled about by the movements of the ship."

On theoretical grounds he advocated the hypodermic injection of atropine and strychnine, because through their action upon the nervous centres and the unstriated muscular fibre the blood pressure is increased. Although the application of remedies in this way had been attempted before, yet he claimed results far better than those previously obtained by any one else, and, so far as I can find out, by any others who have since tried the method.

From experience I can say nothing of these remedies as a cure for seasickness, but even if the writer is not mistaken as to their real efficiency, as very likely he is, they are by comparison heroic remedies, and in any view of the case it is better to prevent than to cure. So far as I can learn, very little systematic experiment has been made by ship surgeons in the preventive treatment of seasickness.

In order to appreciate fully the miseries of the seasick, it is quite necessary for one to get seasick himself. Sailing on the same vessel with myself were Drs. George F. Shrady and Charles McBurney. Both of these distinguished physicians, throughout a severe storm of several days' duration, when almost every one on board was sick, took their meals and smoked their cigars with unfailing regularity. While enjoying their postprandial smoke they could discuss the humorous side of seasickness, and with smiling skepticism express their disbelief in the efficacy of any remedy for its relief. Another physician, on the contrary, was as miserable as a man could well be. His point of view was different, and he listened with the greatest interest to anything relating to the subject, and was eager to try the remedy suggested. This he did on the return voyage, and with results so satisfactory in his own case that he would consider himself culpable if he did not give to others the benefit of his own practical experience.

3d. Still another reason for the apathy that prevails and the general disinclination to attempt anything for the relief of seasickness, is the absolute failure of most of the remedies that have been tried, and one's dislike to subject himself or another to the careful preliminary treatment by the one drug that has proved most reliable. No intelligent physician believes that seasickness comes primarily from the stomach or liver. A person going on shipboard suffering from constipation or disordered digestion is, without doubt, more liable to sickness than if he were in a perfectly healthy condition; but, on the other hand, a person whose functions are all acting harmoniously may, as is well known, instantly succumb to seasickness on encountering a rough sea. The theory that seasickness is dependent upon a functional disturbance of the central nervous system seems the correct one, and upon this theory is based the use of the bromides. The nausea and vomiting come from the brain—an inevitable consequence in certain susceptibilities of the constant series of mild concussions of the brain that are attendant upon the rolling, pitching, and tremor of a ship. Any method, therefore, that will obtund the sensorium, rendering it, in a measure, anæsthetic and insusceptible to slight molecular changes, would seem to be a rational method.

This the bromides will do, and one of the first to

¹ New York Medical Journal, December 2, 1893.

¹ Transverse incision. Patella sawn through. Transverse section of femur and tibia. Patella and bones subsequently wired.

² Patella turned up with flap. Transverse incision of femur and tibia. Patella nailed to femur and tibia. Bones wired.

³ Patella removed, wedge made of femur to fit V-shaped incision of head of tibia. Diseased soft parts sawn away with the bone, saving time. Bone lock, no wiring required.

⁴ Curved incision of bones parallel to articular surfaces saves time by avoiding wiring and nailing.

⁵ Read before the New York County Medical Society, December 23, 1895.

suggest their use in seasickness was the late Dr. Fordyce Barker. Subsequently, Dr. F. D. Lente struck the keynote of the treatment in its relation to this disease, when he advocated the administration of the remedy for some days before sailing. Dr. George M. Heard then took up the subject, and in a clever and exhaustive brochure did more than any other to popularize the method and demonstrate its efficacy.

As to the measure of benefit to be derived from the use of the bromides in every case of seasickness, the exact percentage of cases in which they will act as preventives, I cannot pretend to say, but I do assert that they are capable in many cases of preventing altogether even a suggestion of seasickness, and my opinion, based upon a considerable experience, is, that if properly used, they will prove successful in a large proportion of cases. It has been forcefully said that "the battle against seasickness must be fought on land."

It is not the bromides alone, but bromization, that is demanded, and this must be induced and kept up two or three days before, and continued for several days after, sailing, and sometimes even through the entire voyage. The amount necessary to produce mild bromization varies in individual cases. Thirty grains three times a day may be sufficient, but in many cases it is necessary to give much more than this. Because of its greater acceptability to the stomach, the bromide of sodium is much to be preferred to the bromide of potassium. It is certain that many have failed to experience any benefit from the treatment because of insufficient doses, and in every case where I prescribe it I always see to it, if possible, that the physiologic effects of the drug are obtained.

The fear of seasickness prevents many from availing themselves of the advantages of a sea voyage and the pleasure and profit that come from travel abroad. Personally I had always looked upon the sea with the greatest dread. Few are more susceptible to seasickness. Indeed, I have never been on a vessel of any kind where there was much motion without suffering from intense nausea. For this reason more than any other I had never ventured upon a trip abroad up to last summer, but, encouraged by the good reports that came to me from those to whom I had recommended the treatment, I ventured to go.

For three days before sailing I prepared myself by taking one hundred grains of the bromide of sodium in divided doses in the twenty-four hours, and this I kept up in somewhat lessened doses for the first four days on the water. I was not at all sick. I might not have been sick if no preventive had been taken, for the voyage was comparatively pleasant. Quite a number were sick, and my judgment is that I should not have escaped altogether. The test was not, however, by any means conclusive, even so far as my own individual case was concerned.

Before going, I mentioned to a professional acquaintance what I was about to do, and his reply was that he would rather be seasick than be bromized. My personal experience of bromization, carried only to the moderate extent necessary as a prophylactic, is, that it is agreeable rather than otherwise, for, aside from a slight feeling of drowsiness and inertia, which quickly disappeared when the mind became interested, there was no noticeable effect. An exceedingly satisfactory condition was the soundness and refreshing character of the sleep induced. Idiosyncrasies against the drug are, it is true, occasionally met with, but it is safe to say that very few adults will experience the slightest discomfort from a thirty-grain dose of the bromide of sodium three times a day.

The next test was eminently satisfactory. I crossed the English Channel (the longer route)—having prepared myself by taking the drug for two days before-

hand—with perfect comfort. The sea was very rough, the boat rolled and tossed excessively, and a large proportion of the passengers was very sick. I, however, escaped altogether, and in returning had the same satisfactory experience. I regret to say that on the trip home a smart attack of seasickness was experienced, but this should not in all fairness be attributed to a failure in the action of the remedy. I prepared myself by taking the bromide of sodium in rather lessened doses and for a shorter period beforehand. The first twenty-four hours out were so perfectly pleasant that the remedy was omitted from time to time, until I awoke to the fact that the slight bromization felt on going on board had entirely passed away. I awoke to this fact just as a storm of unusual severity struck us. To make amends I hastily took a large dose, but it was too late, and for twenty-four hours I suffered with the majority. While my carelessness in omitting the drug is to be regretted, yet it in no way destroyed my confidence in its efficacy. On the contrary, I felt, from my previous experience, that had the plan of treatment not been neglected I should have escaped altogether.

While in London I met a lady of my acquaintance from this city, with her two daughters. She told me that on the voyage over, some months previously, all of them were violently seasick, notwithstanding the fact that the passage was by no means a rough one. She dreaded exceedingly the return, and eagerly availed herself of my offer to prescribe for her. She and her daughters took the bromide of sodium according to directions, and although the passage was a stormy one, with many if not most of the passengers sick, these three remained perfectly well, and lost not a single meal.

Shortly after my return, a gentleman consulted me for a neurasthenic condition from which he had suffered much, and incidentally told me of his extreme susceptibility to seasickness and of his great dread of the sea. His business compelled him to take occasional trips abroad, and for weeks before sailing his neurasthenic symptoms invariably became greatly aggravated. It was a question with him whether this morbid fear of the sea was one of the causes of his neurasthenia, or whether his neurasthenia caused his fear of the sea and his fearful attacks of seasickness. Before sailing I subjected him to bromization, combining with the bromide a small portion of chloral.

This is the letter he wrote after arriving in London:

"In fulfilment of my promise I write to tell you the results of the bromide treatment. I went on board with fear and trembling, but am glad to say that I was much more composed than usual. I suppose this was due to the sedative effects of the medicine. As we passed Sandy Hook, and the rough sea began to give to the vessel that horrid motion which I could never think of without a shudder, there came a suggestion of nausea, and for a moment I lost all faith in the treatment. I fully expected that affairs would take their usual course, but to my great delight it was only a false alarm.

"As the ship went up and down, and rolled from side to side, and the hours went by, and I was not sick, I could hardly believe it. It is the first time that I have crossed the Atlantic with even a moderate degree of comfort and without missing a meal, and am more grateful than I can tell."

The foregoing is only one of the letters and statements I have received from those to whom I have from time to time recommended and urged the use of the bromides for the relief of seasickness. Some have never reported and the results I do not know, while on investigating the cases of those who claimed to have received no benefit I almost invariably found that the remedy had been taken with timidity and not at all

according to directions. On the voyage over, one among a party of physicians from the West was quite sick for several days, and promised on his return to try the method and report. In a letter dated November 19, 1895, he writes as follows: "Yes, I did try the bromide treatment, and I must acknowledge that I do not know whether it helped me or not. In the first place, I did not use as much as you suggested—only fifteen grains a day for the day immediately preceding the day we started, and for one day after the journey had commenced. I did not suffer as much coming back as I did going over, although I suffered considerably." It is hardly necessary to say that no possible good could result from such insignificant doses, and it is an excellent, if extreme, illustration of the difficulty of inducing others to carry out correctly even the most explicit directions. If an intelligent physician could so misunderstand and misapply a simple method of treatment, what can be expected of the average patient? The difficulty is that in many, if not most, of the cases where the bromides are used, they are used improperly and in insufficient doses, and without knowledge or forgetful of the fact that it is not so much the bromides that prevent seasickness as bromization.

THE EFFECT OF COLORED OR DECOMPOSED LIGHT UPON THE NERVOUS SYSTEM.

By COLUMBUS DREW, M.D.,

JACKSONVILLE, FLORIDA.

PURE composite light is invisible, hence all light, as we experience it, is as a result of refraction, reflection, or transmission to some degree decomposed, apparently from design upon the part of nature that we shall not be subjected to the action of pure light, any more than we are permitted to drink pure water.

There are certain subtleties in nature, apparently intended to reach the psychical, and through it the physical organization by means of the special senses. The agent of this character best studied and supposed to exert the greatest influence upon the nerve forces is sound. In its various modifications it exerts remarkable influences upon all vital structures, not only among reasoning creatures, but also upon those possessing the crudest instincts and most savage natures. Indeed it is a question as to whether the appreciation of sweet sounds and brilliant colors is not proportionately better developed in some of these creatures than in those of higher organization. There are few creatures of lower degree in our little world than serpents, and their fondness for music, even such as to us seems to have but little harmony or sweetness, is well known, and these creatures can be so seduced by it as to be lulled into forgetfulness of their means of defence and to submit to capture. Upon an occasion at St. Augustine, Fla., the army band was discoursing delightful music upon the barrack grounds, the sounds being borne by the winds across the waters of Mantanzas Bay. Lured by the sweet sounds an alligator made his way to the surface, facing the band, where he remained regardless of repeated shouts and warnings, disappearing to return again and again, until a marksman, failing to appreciate the interest of the occasion, fired a shot into his brain.

Accordant sound has long been used by Evangelists to draw wayward temperaments from ways of evil, and it is well known that hearts of stone can be moved to most repentant tears by such sounds; and such is their influence upon the organization and the molecular nerve structure that the effect will in many in-

stances endure throughout a lifetime. The laggard and trembling soldier, pale with nervous apprehension, trembling in every fibre, under the influence of music becomes a hero. Scarcely will the soul-stirring sounds of the Marseillaise reach the ears of the Frenchman, or those of Dixie or the Star-spangled Banner those of an American, before a mystic change occurs. The vital knot, the soul centre stirred, the contracted capillaries dilate, and the vital fluid, which nature sends to the brain in order to sustain vitality, courses throughout the entire organization, and the man becomes a changed being; no longer a lamb but a lion.

Wedding-bells, with their cheerful notes, convey a sense of happiness and well-being; but a frame of mind, cheerful and happy, may be changed to melancholy by the notes of a funeral dirge. The effect is associated with those mystic influences to which are allied the sensations of shame and anger, obscure crime, etc. The following excerpt will illustrate some of the remarkable relations existing between color and sound.

"Sound of a Sunbeam.—One of the most wonderful discoveries in science that have been made within the last year or two is the fact that a beam of light produces sound. A beam of sunlight is thrown through a lens on a glass vessel that contains lampblack, colored silk or worsted, or other substances. A disc having slits or openings cut in it is made to revolve swiftly in this beam of light so as to cut it up, thus making alternate flashes of light and shadow.

"On putting the ear to the glass vessel, strange sounds are heard so long as the flashing beam is falling on the vessel. Recently a more wonderful discovery has been made. A beam of sunlight is caused to pass through a prism so as to produce what is called the solar spectrum or rainbow. The disc is turned, and the colored light of the rainbow is made to break through it.

"Now place the ear to the vessel containing the silk, wool, or other material. As the colored lights of the spectrum fall upon it, sounds will be given by different parts of the spectrum, and there will be silence in other parts.

"For instance, if the vessel contains red worsted, and the green light flashes upon it, loud sounds will be given. Only feeble sounds will be heard if the red and blue parts of the rainbow fall upon the vessel, and other colors make no sound at all. Green silk gives sounds best in a red light.

"Every kind of material gives more or less sound in different colors and utters no sound in others."—*Pierson's Weekly*.

But little has been written as to the occult influence of the other special senses upon the physical organization—the stimulation of the sense of smell, or that of color perception—and still it is difficult to believe that such delicately organized structures are only intended to excite sensations of pleasure, when such sensations could be so happily combined with other influences calculated to improve health and to encourage physiological function. What is better calculated in a hungry man to give rise to a healthful secretion of gastric juice than the odor of a good stew? And can such stimulation of the pneumogastric nerve occur without a corresponding stimulation of the cerebral circulation and a corresponding effort upon the part of other organs? If these two special senses of sound and smell exert an influence over the organism, it is quite as likely that sight and the color sense should do the same. It is a philosophical fact that color in light corresponds to pitch in sound; the red rays are said to be the longest of the colored ones and correspond to sounds of low pitch, violet rays are the shortest and correspond to sounds of a high pitch. In

other words, red corresponds to grave and violet to acute sound.

Sunshine certainly exerts a most necessary and beneficial influence, and without sunshine there can be no color, whatever may be the theories of color sense and color blindness. It seems probable that decomposition of light is the result of refraction or reflection from atoms or molecules in varied positions. In transparent matter refraction occurs by transmission, in opaque bodies by reflection, hence if there is neither transmission nor reflection there can be no light. It seems to be as unreasonable to expect a series of nerves for the recognition of various colors as it would be to expect a series for the recognition of the varied sounds of music, etc. Stand below the mountain top, and view the light rays passing through the vapor in the clouds as the sun sinks below the horizon, and they will be decomposed into the seven colors of the solar spectrum as a result of the position and angle taken by the molecules of vapor, as the rays of light enter and leave them. The same phenomenon, of course, creates the rainbow. Again, as the light falls upon familiar objects, sea water with its chlorides, green or red leaves, grass, flowers, etc., reflection at various angles will occur, resulting in decomposition of light and such sensation of color as may be the result of the impact or chemical action of rays of varied length and power upon the retina.

If we study the sects, nations, society, etc., of the world, we cannot fail to notice the association of dress, and the correspondence of colors and habili-ment, with disposition and character. We see in the sects of grave, religious character and disposition the absence of bright colors, combined with inconspicuousness of cut and in strong contrasts with the out-fits of the worldly and gay. In the lower and middle classes of certain nations who have not been accustomed to serious personal responsibilities, but have from childhood remained accustomed to pastimes and amusements, the people retain and exhibit in their garments evidences of fondness for brilliant colors and combinations, in connection with happy and childlike dispositions. Upon occasions where joy, festivity, and happiness are intended, a blending of color and sound is instinctively sought. In both fair and ball-room the sounds of sweet music and pleasing alternations of color are blended in order that the combined effect may stimulate the nerve centres, and the faculty of enjoyment be roused to its highest pitch. The following excerpt from the daily press will establish the marked influence exerted by color upon nerve structures in creatures ungoverned by reason:

"Attacked by a Mad Bull.—Newark, N. J., May 21st.—A maddened bull, while being led by T. W. S—to-day through the streets, attacked and lacerated Mrs. Susan B—, a servant, who was wearing a red shawl. The bull was being led by an iron chain when he broke away. The woman will die."

It seems to be intense, even maddening. The wearing of a red garment while in the vicinity of the bo-vine species has always been regarded as dangerous, and at the Spanish bull fights they are favorite means of arousing the anger of the animals.

Some years ago General Pleasonton, a resident of Philadelphia, advanced a theory that the action of decomposed light was valuable in the treatment of disease. Blue was possibly the element looked upon with greatest favor. For some time it was the custom to insert panels with blue glass into houses for the purpose of using the treatment, but as no system was adopted and no definite results were obtained, the fashion had its day and disappeared. The following excerpt is on the same line of thought:

"Color in the Home.—The modern scientific deco-

rator assures us that while yellows are all right for a hall or vestibule, they should not be used in rooms where one reads or works. The reason assigned is that yellow does not absorb light, but is a strong reflector, and these reflected rays are trying to the eyes, but, more than that, are distinct brain disturbers. For the library or work-room the most soothing or satisfactory tint is coffee.

"The influence of color upon temperament or physical condition being an accepted fact, it follows in natural sequence that the treatment of living-rooms is of real importance. Undoubtedly some natures respond quicker to these influences than others, but any one planning a change in furnishings will do well to give the matter some attention."

A recent number of the *Boston Transcript* contains the details of experiments by Professor Bailey, of Ithaca, N. Y., with colored lights upon growing plants. The experiments showed remarkable results as to growth and development under the influence of colored light. The details would be too lengthy to narrate in this article.

To influence life and character by means of color is simply to influence by means of light, as color is the result of decomposition of light, certain elements only being represented in any given color.

In the world of music, George Holmes, in *Munsey's Magazine* for August, 1895, publishes the following:

"Within the past few weeks a 'color organ' has been constructed. The rates of vibration of the light waves that produce different colors are said to vary in much the same ratio as the intervals in the sound vibrations that produce musical notes. The inventor of the color organ plays the music of the great composers upon the keyboard of his instrument; but instead of producing sounds, colors corresponding to the notes are thrown upon a screen making rare harmonies in tints."

If this prove to be an accomplished fact, and such seems to be the case, we are approaching the time when the effect of color transition, as of sound, upon the nervous system may be tried in the treatment of disease. In the present state of our knowledge little would probably be accomplished in the treatment of acute diseases, but in the management of chronic affections of the nervous system such as neurasthenia, melancholia, etc., it would be well worth a trial in connection with other treatment.

In the construction of sanitariums, kindergartens, etc., an apartment arranged for such experiments would appear to be, like the solarium, a desirable adjunct.

Early Intestinal Anastomosis.—Dr. Gamgee, writing to the *Lancet*, says that he recently, in South's translation of "Chelins' Surgery," published in 1847, came across the following words: "In complete division of the intestine Denans introduces into the upper and lower end of the gut a silver or zinc ring, thrusting it in inwards about two lines from each end; he then brings the two ends together over a third ring, of which the two springs retain the external rings. The included ends of the intestines mortify, and the rings thereby becoming unfastened are discharged by stool after they have united the serous surfaces in contact. This experiment in the dog has most successful results." Chelins gives as his reference "Recueil de la Société Royale de Médecine de Marseille, 1826." "The resemblance which the above-mentioned instrument must have borne to the modern Murphy's button is," says Dr. Gamgee, "remarkable, for while its mechanical details were evidently strikingly similar its mode of action must have been precisely the same. Truly there is nothing new under the sun."

SHOULD OUR HOSPITALS EXTEND THEIR FACILITIES FOR OPERATING TO PHYSICIANS GENERALLY?'

By HENRY S. STARK, A.M., M.D.,

NEW YORK.

In presenting a paper of this character in lieu of a scientific one, a word of explanation would be in order. This paper was not written to satisfy a morbid desire to appear in print, nor yet to crave or court notoriety. Nor is this paper a literary effort, for if the question that I shall submit to your consideration is wrong in principle, beauty of language will not save it; if, however, it is sound in principle, homely diction will not rob it of its interest or importance.

I would call your attention to-night to a matter which should appeal not only to your heart and conscience but also to your purse and pocket. Questions of an ethical, or economical, or of a medico-legal character are rarely brought forward for discussion at our medical meetings. Very rarely does a topic of such a character appear as part of our programmes, and yet no one will deny that such matters are of the most vital interest to us.

I firmly believe that each medical society in this city and elsewhere should devote at least one meeting in each fiscal year to the discussion of a question which involves our rights as medical men, or deals with our relations to the public or with each other. Such an innovation would afford the members of the profession an opportunity to ventilate their grievances, adjust their difficulties, and reconcile their individual differences in a legitimate and at the same time strictly professional manner, and would render it unnecessary to resort to the columns of our newspapers, as too often obtains, for a hearing or for adjudication.

The title of my paper conveys the idea of the subject-matter. I shall claim that the boards of managers of our hospitals should throw open their doors to physicians generally, and thus allow them to perform operations upon their private patients in the operating-rooms of these hospitals, under certain restrictions and limitations which I shall mention later on. Here I find it necessary to observe that I do not advocate the extinction or retirement of the visiting surgeon, for his position in the medical community is fixed, and it is foreign from my present purpose to infringe on his rights and immunities; but I simply take the ground that the use of the operating-rooms when not otherwise occupied should not be limited to the visiting staffs to the exclusion of all others. That this is a radical and startling departure from the present régime is very apparent, but that fact alone should not militate against its introduction under suitable conditions. I am fully alive to the fact that in advocating a sweeping change like the one proposed, I shall antagonize some so severely that I shall be, in the language of diplomacy, "*non persona grata*" to not a few, but I could not for a moment allow the fact that I shall incur the displeasure of any one to act as a barrier. Remember that every new movement, every new enterprise, every new law or reform, subjects the prime movers to unjust criticism and unfavorable comment. Therefore all honor to the man who, when his cause is just, dares to brave public opinion, stands alone against fearful odds, and faces opposition unflinchingly.

There are four sides to this question. There is the physician's side, the visiting surgeon's side, the side of the public at large, and the side of the hospital managements. It would certainly be interesting, to say the least, if all concerned would come forward

with an expression of their opinion, without fear or favor.

From the physician's standpoint, it may be claimed that the members of the profession are constantly laboring under a baneful disadvantage when they find their field of usefulness limited in diseases requiring surgical interference. For directly they decide upon the necessity of an operation, their connection with the case ceases. If the board of directors of our hospitals would extend the privileges of the operating-rooms to the physicians throughout the city, just think of the advantages that would accrue to us. Physicians would not be indirectly compelled to let their remunerative operative case slip from them and fall into the hands of disinterested colleagues, who happen to be hospital surgeons, and who thus reap a harvest out of our own cases. Mark you, I am not alluding to such cases in which, on account of the nature of the disease, extraordinary skill and experience are required. I am now referring to such operative cases as do not call for unusual skill, cases which we feel we can handle with the same skill as those on the regular hospital staffs.

Day after day, physicians see their operative cases enter hospital wards simply because all the paraphernalia of the operating-room are not available, nor within the means of their *clintèle*. Does not this sentiment touch a responsive chord in your bosom? I fancy it does, for many of you have met and are constantly meeting with such unpleasant experiences and are sighing for relief and redress. In these days of advanced surgery—what with aseptic operating-rooms, aseptic operating furniture, aseptic assistants, instruments, and dressings—what physician in private practice can keep pace with the enormous outlays connected with an operation which is expected to be done in a *fin de siècle* manner?

Another advantage to physicians in general would be the opportunity for acquiring operative skill and a knowledge of operative technique. To-day this advantage is monopolized by about fifty out of thirty-three hundred physicians. The number of physicians to-day who never touch a knife is legion. Why? Because they would rather not operate at all than to operate with imperfect and insufficient apparatus. Give some of these physicians an opportunity, and they will take up the knife and wield it as skilfully as some who have had a lifelong connection with a hospital. How many physicians are there who are sufficiently skilled in operative technique to warrant them to undertake major operations with reasonable hopes of good results, providing they had a suitable place to operate? They have the skill, the knowledge, the courage, and, what's best of all, the patients—but not the room. Placing the figures at a low estimate, I am justified in stating that a physician who has a yearly income of \$3,000 is forced to surrender five to ten operative cases each year for lack of accommodations, while a physician with a \$5,000 yearly income refuses for the same reason ten to twenty operative cases. Now will some one suggest a remedy for this evil and a relief from such oppression other than the one proposed? I have no hesitation in saying that I am voicing the sentiments of many here to-night and many who will read these remarks after publication.

A few words relative to the position of our visiting staffs of surgeons, for almost all opposition that this question will give rise to will emanate from that source. I do not anticipate that they will acquiesce in such a measure complacently; such an expectation is neither natural nor probable, for this improvement in hospital management, if carried out, would prove detrimental to their interests. The position of visiting or attending surgeon in New York is a unique one, in so far as it provides these selected and favored few

' Read at the November meeting of the Metropolitan Medical Society of New York

with all the facilities of a private hospital, with the exception that all expenses incurred in its maintenance are encountered by one side, the hospitals. Truly a much envied position. In former days the main function of a visiting surgeon was to treat the cases as he found them in the hospital; now much of this is changed, and his main duty, it appears, is to utilize the private rooms and even the wards of the hospital for the cases that he sends in from his private office, and in other instances from his public clinics. The hospital receives no returns in such instances, while the surgeon is handsomely reimbursed, and has not a cent of expense connected with the treatment. This is neither an exaggerated nor an overdrawn picture, but the solemn truth, which many of you could substantiate if called upon to do so. This system is so extensively practised in New York that I actually know of one hospital, the directors of which were compelled, for their own protection and for the interest of their trust, to adopt a law whereby a visiting surgeon was not allowed to utilize more than two private rooms at any one time for his own private patients. I know of one surgeon who, when asked why it was that he had not his own private hospital as his rival colleague had, stated that he did not see the necessity of burdening himself with such an expensive luxury so long as — Hospital, with which he was connected, furnished him with all such facilities and free of all expense. Now ask yourselves, is it right, is it fair that a visiting surgeon should be permitted to utilize a hospital's facilities in such a manner to the exclusion of all other physicians? To use mild language, it is un-American and savors of monopoly. Here some one will say, that the members of the visiting staffs give their eminent services gratuitously to the institutions. True, but are they not reimbursed in a great measure in manifold ways that I need not enumerate here? Why, tell me, are these positions so eagerly sought for if there are no emoluments connected with them? Needless to answer that question now, the reasons are painfully familiar to all. Is it not a notorious fact that, even when not actually on service in the hospital, the members of the visiting staff send in, and operate upon, their own private cases? Now why not remedy this discrepancy in a measure by extending the same privileges to physicians who have the ability to operate?

As far as the public is concerned in this matter, there is this to be said, that it has a right to expect the best services from both the hospitals and their officers irrespective of the question of remuneration, especially in institutions that are being subsidized from the city's revenue. We are constantly told by professional *opérateurs* that it is not justifiable in certain instances to perform major operations in tenement-houses or in private houses, even if the occupants can surround themselves with all the resources of modern surgery. This stand has been taken so frequently that even the public is educated up to it. Where, then, let me ask you, are we to perform them unless the hospitals come to our relief in the manner indicated by my remarks? The expenses connected with a house operation, if done *lege artis*, are in many instances a burden to the parties mostly interested. Often its performance entails hardships and sacrifices which only those of you are familiar with whose practices bring them in contact with the middle and lower strata of society. Now the expenses in connection with an operation would be reduced to a minimum if the system I advocate were adopted; while scores of patients who otherwise under the present *régime* would be admitted without paying for services rendered by the surgeon, would gladly in many cases pay their doctor for the work done at a hospital. So you see the old or rather present system actually pauperizes the public and fosters

an abuse from which medical men in this city and elsewhere are crying for relief, and which, if allowed to continue, bids fair to menace their prosperity and chances of livelihood. Indeed, so keenly alive is public feeling toward the gratuitous services offered by our public institutions, that directly an operation is indicated, patients rush to the hospitals and clamor for admission, utterly disregarding the fact that they may be in a position to pay for treatment.

A few words in regard to the position of our hospitals on this question. I take it for granted that you are ready and willing to admit that the broad general principle of economy which should govern our hospitals is "the greatest good for the greatest number," irrespective of individual or class feeling. If that be so, why should not our hospitals allow other men than those of its own staffs the privileges of operating? For the more physicians to avail themselves of such advantages, the more patients credited to the institution, the greater the amount of good done, the more suffering relieved, the more cures effected, the greater its revenue—in short the whole field and scope of its usefulness would spread in all directions, it would become a public benefaction in the broadest and most liberal sense of the word. Hospital authorities should not be guided in a universal reform measure like the one contemplated by the opinion of their visiting staffs alone, since they form, numerically, a very insignificant part of our medical community. Let such authorities make public opinion the criterion for their conduct. Let hospital officers bear in mind that in matters purely executive and administrative they should be superior to professional men. What would happen if, for example, "— Hospital" should adopt such a reform as the one under discussion? Its visiting staff would probably resign in a body. Their places would be filled with probably equally competent men in a comparatively short time. The chances are that the public and the profession at large would indorse the action of the directors, and would lend the institution their moral support and sympathize with the movement. Who would be the loser and who the gainer by such a hypothetical case, I need scarcely point out.

From the standpoint of the hospital the most important aspect of the question is its practicability. I believe the change is practicable under certain conditions, which I shall enumerate.

Firstly, such a change might render necessary an auxiliary operating-room; a contingency already provided for in several of our better-equipped institutions.

Secondly, it would be expected that each operator would be accompanied by his personal staff of assistants except nurses and operating-room attendants.

Thirdly, it would be expected that a nominal fee would be imposed upon all physicians who availed themselves of a hospital's facilities.

Fourthly, on visiting their patients subsequent to the operation, physicians need not necessarily be attended by the member of the house staff.

Fifthly, patients would be expected to reimburse the hospital for services rendered.

This, then, is a brief *exposé* of the object intended to be accomplished. Truly "a consummation devoutly to be wished." But how shall this hospital reform be brought to a successful issue, and who should take the initiative? At present, I know there appears to be an impregnable barrier. One word, however, in to our language solves the mystery at a stroke—"Organization."

A society should be organized whose one and only object should be to bring this reform to a successful issue. Ways and means for the success of such an organization could almost be guaranteed. Once such

an organization is effected, its membership would speedily assume such proportions that in a very short time a powerful and formidable influence could be exerted in divers ways upon those in control of our hospitals and upon those opposed to this reform. Once the question is agitated and the public and the profession instructed in the advantages of the measure, it would not be very long before one of our more advanced institutions would try the experiment. Once let physicians conquer their indifference and bury their disinterestedness, and you cannot begin to conceive how easily their object may be accomplished. Once a leader is found to pioneer the movement, recruits would flock from all four sides to advance the cause with all their hearts and souls.

270 EAST SEVENTH STREET.

Progress of Medical Science.

Toxin Injections for Malignant Growths.—In the *Münchener Medicinische Wochenschrift*, September 3, 1895, Czerny describes his experience with the treatment of malignant tumors by injection of mixed erysipelas and bacillus prodigiosus toxins (prepared according to Coley's method).

Although the influence of accidentally contracted erysipelas in cases of carcinoma has in his experience usually been a negative or distinctly adverse one, he recalls two instances in which the effect of the erysipelas was distinctly beneficial. One of these occurred in a woman who had undergone seven operations at the hands of three surgeons for carcinoma of the breast. She applied to Czerny for the eighth operation. As the chest wall was thoroughly infiltrated, he advised against operation, but at her request he dissected away as much of the growth as possible—leaving a wound as big as a saucer, with a carcinomatous base. Erysipelas set in, and the patient was brought to the edge of the grave. The cancerous nodules disappeared, and in eight weeks the wound was completely healed. Two years later the patient died apparently of broncho-pneumonia, her health in the mean time having been good.

At the autopsy, the chest wall and axilla were found absolutely free from cancer, but the right lung contained many cancerous nodules which were considered to be the cause of death.

The other patient had undergone two operations for cancer of the breast before Czerny saw her and removed recurrent nodules. Erysipelas followed, and six years later there had been no further recurrence of cancer.

Czerny's experience with the toxins began in May, 1895. He has treated eight cases, four of sarcoma and four of carcinoma, making use of a mixed culture of erysipelas and prodigiosus cocci sterilized by heat. The most marked effect was in the following case:

Mrs. B—, aged thirty-five, had had for five months a rapidly growing tumor of the right parotid region, extending back of the ear, giving rise to complete facial paralysis of that side, and having reached, at the time the injections were begun, the size of a man's fist. It was firm, nodular and ulcerated in places, and had the clinical appearance of an infiltrating carcinoma of the parotid region. Microscopically it was found to be a small round-celled sarcoma, containing scattered typical nests of epithelium and pearls. In six weeks eighteen injections of erysipelas toxin were made, with marked constitutional symptoms—pain, chills, and fever up to 40° C. (105° F.).

At this time the facial paralysis had nearly disappeared, the parotid had become soft, and the infiltrating tumor had dwindled to three soft nodules movable

in the skin, and all measuring about an inch and a half by half an inch.

Czerny considers this case an illustration of the favorable, almost specific influence of the toxins on a malignant tumor; but does not consider it an absolute proof, since the patient at the time of treatment was pregnant, and similar tumors (sarcoma, epulis, fibrosarcoma of the abdominal wall, osteophytes of the skull) often disappear in part after confinement.

The case was still under treatment at the time of the report.

The other cases of sarcoma were handled only a short time and showed only slight change.

The four cases of carcinoma were treated without benefit, except that in one case—a carcinoma of the upper jaw of wide extent—after eighteen injections the tumor was softer and the subjective condition had improved.

The author closes as follows:

"As already said, the material is too scanty and has been handled for too short a time to permit of the deduction of rules for the treatment of malignant tumors. None the less the fact that many tumors are favorably influenced by erysipelas toxins seems to me so important that it appears desirable to test this influence in every way. If it comes to pass that many tumors otherwise incurable—as, for instance, the sarcomata—can in this way be treated methodically and cured, that of itself will be a great gain; and an insight into the other malignant growths will also be won, although doubtless considerable water will flow down the valley of the Rhine before this thousand-year riddle of the Sphinx is solved.

"However, these injections of sterile mixed cultures are of the greatest interest from a general pathological point of view, and, grouping my limited experience with the much wider experience of Coley and others, I draw the following conclusions:

"(1) The sterile, unfiltered, mixed cultures of erysipelas and prodigiosus cocci when injected in minute quantities produce a rapidly rising temperature, often with chill, gastric symptoms, dizziness, and delirium; sometimes with herpes labialis, but usually without local inflammatory symptoms. The intensity of these symptoms depends on the individual, on the amount of the dose, and finally on whether the fluid enters the lymph spaces or the blood-vessels (Repin).

"(2) These symptoms subside in a few hours without permanent effect upon the general condition. After the injections have been many times repeated, there appear anorexia, emaciation, anæmia, and malaise.

"(3) The injections are capable of exercising a specific influence on sarcomata which, under favorable circumstances, they may cure (Coley).

"The tumors become œdematous, and then simply shrivel up and are absorbed, or else, softening, necrosis, and sloughing of the tumor tissue take place.

"(4) As the results are still wholly uncertain, this method of treatment cannot take the place of operation, much less become preferable to it. For the present it is to be employed only in cases of inoperable or recurrent tumors. Perhaps after operation for sarcoma it may be used to guard against recurrence.

"(5) In carcinoma the injections produce at most a delay in the growth, but no cure."

Diseases of the Liver Caused by Syphilis are:

(1) a perihepatitis with such extensive cicatrization that it is impossible to tear away the adhesions; (2) an amyloid degeneration; (3) gummata; and (4) a diffuse interstitial hepatitis. In the latter the liver preserves its form and volume, but an embryonal tissue springs into existence and develops with such strides that the liver tissue proper disappears. This new

embryonal tissue does not atrophy as in cirrhosis. The whole organ becomes hard and polished like carved ivory. The development is slow and mostly painless. At times icterus is noted, as well as ascites and enlargement of the spleen. Cure is till now unknown.—LISTEN, *Berlin Society of Dermatology*.

Apparent Contagion of Psoriasis.—In spite of the seeming success of Destot's inoculations, the contagiousness of psoriasis has not been accepted. Dr. Méneau (*Journal de Médecine de Bordeaux*, December 15, 1895) relates a case in which a psoriasis in a girl of eight years was followed after three years of existence by the same disease upon the scalp of a younger sister who had been in the habit of using the first patient's comb.

Comparative Gravity of Genital and Extra-Genital Chancres.—Syphilis following extra-genital chancre may present at times unusual features of gravity. When we collect a very large number of cases, it is seen that the gravity of syphilis of extra-genital origin is the same as that of syphilis of genital origin. The gravity of certain cases of extra-genital syphilis pertains much less to the localization of the chancre than it does to the conditions of the soil upon which it develops.—FOURNIER, *La Tribune Médicale*, December 25, 1895.

Pharyngeal and Laryngeal Adhesions and Strictures in Syphilis.—Dr. Heymann writes that syphilitic strictures of the pharynx have two sites of predilection—the neighborhood of the posterior nares, and the limit of the buccal and nasal pharynx, where they take the form of adhesions of the velum palati to the posterior wall of the pharynx. These adhesions are of cicatricial character. Stenoses are found in the lower pharynx, though always with a central orifice which may be very small and cause considerable difficulty in swallowing. Syphilitic strictures of the larynx are due to several factors: infiltration of mucous or submucous tissue, gummatous ulceration, crico-arytenoid arthritis, condylomata, isolated or superimposed cicatrices. The cicatrices are situated generally near the vocal cords. Syphilitic treatment sometimes arrests the sclerotic process; in other instances it has no effect. Once established, the cicatrix may be attacked in different ways—the galvanic knife, cutting-forceps, dilatation, or intubation.—*Revue de Laryngologie, etc.*

The Treatment of Lumbago.—Dr. Albert Robin speaks of the different local applications with friction, the revulsives, counter-irritants, and wet-cups, which have been used from time immemorial. He mentions more especially massage of the joints and electricity for the secondary muscular atrophy, and methyl chloride for the acute stage. He recommends jaborandi for the internal treatment. Any disturbance in the cardiac rhythm should be considered as a contraindication to its use; also if epistaxis occurs or the quantity of urine does not reach the normal amount after diaphoresis. He prepares the jaborandi by macerating sixty grains in two and one-half drachms of alcohol for twelve to twenty-four hours and pouring on the mixture one and one-half ounces of boiling water which is infused for twenty-four minutes and then filtered. This filtrate is to be taken hot in the morning after fasting. The patient should avoid swallowing the saliva during perspiration, as it causes nausea and sometimes vomiting. He should drink only small quantities of warm liquids, for instance, coffee, which may relieve the vomiting caused by the ingestion of cold liquids or by swallowing a certain amount of saliva. A single dose of this medicine has been known to cure the disease. When it is expedient to repeat

the treatment it is well to permit a day to elapse between the doses. The patient should be confined to his room or bed and kept warm. Sodium glycerophosphate, five to seven grains, should be administered hypodermically when the above remedy is contraindicated. Sodium salicylate may be used when the articulations are affected.—*Bulletin Général de Thérapeutique*, 1895, p. 241.

Analgesia of the Ulnar Nerve.—Biernacki discovered that in tabes pressure on the trunk of the ulnar nerve in the ulnar groove failed to produce the unpleasant sensation thus produced in healthy persons. Cramer examined a number of cases of mental disease, and found that the reaction was more or less distinctly present in three-fourths of all cases of the non-paralytic insane, but that there was ulnar analgesia on both sides in 39 out of 51 paralytics, or 76 per cent. Snell examined 100 cases, 25 of which were paralytics, and found that in regard to the reaction patients may be classified as follows: 1. Those with normal sensibility as regards pressure in the ulnar groove. 2. Those with no sensibility. 3. A class in which the reaction is weak or different in the two arms. For the 25 paralytics the results were: sensibility normal in 1, weak in 10, and absent in 14. For the 75 non-paralytics the reaction was normal in 25, weak in 39, and absent in 11. Further examination seemed to prove that ulnar analgesia is not related to paralysis except when severe lesions of sensibility are present. As a rule, in the non-paralytics other severe disturbances of sensibility were combined with analgesia of the ulnar nerve. Observations so far as published seem to indicate that ulnar analgesia is of more frequent occurrence in paralysis than in other mental diseases.—*Berliner klin. Wochenschrift*, No. 42, 1895.

The Relation between Tabes, General Paresis, and Spinal Syphilis.—Nageotte has studied the pathology of a number of cases of general paresis, tabes, and spinal syphilis, with reference to the character of the lesions. He finds certain inflammatory changes of a chronic character in all cases, and the nature of the process the same in all three diseases, and he consequently thinks the three separate clinical pictures are merely due to the preponderance of the inflammatory process in certain locations. He concludes as follows: 1. In tabes, general paresis, and syphilitic myelitis, there exists a diffuse inflammatory process involving the whole cord. This lesion, on account of the tissues it seems to attack at first, should be called vascular or connective. It consists of a round-cell infiltration invading the pia mater, the arachnoid, and the capillaries of the spinal cord, and it attacks the superficial veins with great avidity. The essential elements of the cord undergo secondary alterations. The lesion appears to be constant if suitable elective nuclear dyes are employed for its detection. 2. The lesions of the central cortex—causes of general paresis; those of the radicular nerves—causes of tabes; and the localized foci of syphilitic myelitis are only exaggerations of this diffuse lesion in certain points of election, the determination of these points of election being due to factors still imperfectly understood. 3. The process presents a characteristic aspect which seems to make it a distinct entity, although we cannot assert that it always arises from the same causes. From a clinical standpoint, however, it is quite certain that a vast majority of cases have a direct connection with syphilis.—*Archives de Neurologie*.

Pyloric Obstruction from Gall Stones.—Galliard comments on the rarity of this condition and the greater rarity of its appearance at the autopsy table. He mentions several cases where faceted gall stones had been vomited by a patient or passed by means of

a stomach tube. The mechanism of the obstruction seems to be variable. In some cases the stones ulcerate into the stomach, adhesions having been formed, and then get into and close up the pylorus. When adhesions have formed between the pylorus and the gall bladder, the pylorus becomes a fixed point, and, as it cannot recede before a gall bladder distended with stones, the pyloric lumen may be occluded by their pressure. Again, in other cases adhesions form between the stomach and gall bladder and by their own power of contraction close the pylorus. The occlusion may be only partial at first, but as the pylorus is fixed, the stomach, when it becomes distended, drags more and more upon it, and thus increases the occlusion. Unless gall stones are vomited or brought up by the stomach tube, such cases would be difficult to diagnose.—*La Presse Médicale*, October 5, 1895.

Contusions of the Lungs.—Contusions of the lungs, without wounds of the chest walls or fracture or dislocation of the ribs, are not rare accidents; yet the text-books say nothing about them. It is, therefore, of interest to briefly review the main points brought out by Professor Parmenter. Every organ, the heart, the pericardium, the aorta, and the œsophagus, has been injured by apparently trivial blows on the chest, and the lungs do not escape. The elasticity of the chest walls permits a considerable incurve and rebound without permanent injury. The elastic lung would also escape, were it not, as Gosselin has pointed out, that a person about to be hit instinctively closes his glottis, prevents the escape of air under the impulse of the blow, and makes the lung, for the time being, a solid body. The delicacy of the tissues, and especially of the capillary blood-vessels and air sacs, together with the fact that the two pleural surfaces are in exact apposition in a normal state, suffice to explain the serious nature of these injuries. Jobert distinguishes three degrees of bruises. In the first the capillaries only are ruptured, the pulmonary tissue is not torn. In the second the alveoli, bronchioles, and vessels are torn, and blood depots are scattered here and there through the lung. In the third the bronchi and large vessels are torn. Bruises of the first and second degree are usually recovered from; but the patients often die very rapidly from those of the third. Certain complications, chief among which are hæmothorax, pneumothorax, and emphysema, are common in severe contusions of the lung. The symptoms in a severe case are those of shock and collapse, with dyspnoea and profuse hæmoptysis. There are sonorous râles, absence of vesicular murmur, with amphoric breathing and metallic tinkling. Various complications are almost certain to occur in a severe case. They are broncho-pneumonia, traumatic pneumonia, gangrene, pleurisy, etc. The prognosis depends on the degree and extent of the injury, and its complications. Recovery follows if the lesions remain aseptic, and they usually do, even if hæmothorax and pneumothorax are present. In the treatment of the graver forms of contusions of the lungs, the shock must be combated by hypodermatic injections of brandy and ether, and the application of warmth to the body. For the pain and dyspnoea, morphine subcutaneously often acts magically, and may be assisted by the use of cold locally. The hemorrhage frequently demands immediate attention. Auto-transfusion by elevating and bandaging the patient's extremities should be at once employed. If this, with absolute rest in the recumbent position, does not relieve the bleeding, and the dyspnoea and the cardiac embarrassment increase, it is imperative to relieve the condition. With a medium-sized trocar, and using the strictest antiseptic precautions, enough blood may be removed to diminish the pressure. If, as is frequently the case, the

cannula becomes clogged with clotted blood, we must operate as for empyema, and turn out the clots. Unfortunately this frequently starts up the hemorrhage again, and is only to be resorted to when the patient's life is in imminent jeopardy. Pneumothorax can be relieved by paracentesis. Emphysema requires long and deep incisions into the swollen area, followed by judicious pressure. When empyema occurs, it must be treated in the usual manner.—*International Journal of Surgery*.

The Clinical Value of the Phenylhydrazin Test for Sugar in the Urine.—Dr. Williamson discusses the clinical value of the phenylhydrazin test for sugar, and draws attention to a very simple method of performing the test. A test tube is filled for about half an inch with hydrochlorate of phenylhydrazin in powder, then for half an inch with acetate of sodium in dry powder; the tube is half filled with the suspected urine, which is boiled for two minutes. It is allowed to stand, and the deposit examined some hours later. If sugar be present the deposit contains numerous clusters of needle-shaped crystals of a bright sulphur-yellow color. If performed according to the above simplified method, phenylhydrazin is a most valuable confirmatory test for sugar in the urine; the reagents keep well. The test is very easily performed and is very suitable for clinical work. It is very sensitive—more sensitive than Fehling's test and the fermentation test—and will give a distinct reaction with diluted urine containing 0.015 per cent. of sugar. But it is not too sensitive and gives no reaction with normal urine. If in performing the test the test tube is heated in a water bath (as is usually recommended) the method is somewhat troublesome for clinical work; and by prolonged heating very minute yellow crystals can be obtained in normal urine. Hence the latter method is too sensitive for clinical work. The nature of these minute crystals is somewhat doubtful, but their formation is prevented by the action of yeast on normal urine for forty hours. If the simplified phenylhydrazin test gives no reaction with a urine that reduces Fehling's solution, then the reducing substance is not sugar. Many substances besides sugar reduce Fehling's solution slightly (uric acid, creatinin, hippuric acid), but give no reaction with phenylhydrazin. Besides the various forms of sugar, glycosonic acid and pentose form yellow crystals with phenylhydrazin, and also reduce Fehling's solution; but their occurrence in the urine, except as the result of the administration of some drug or in the slightest trace, is exceedingly rare. The great value of the phenylhydrazin test (simplified method) is as a negative test. A urine which gives no reaction may be declared quite free from sugar for all practical purposes.—*Medical Chronicle*.

Hydrocystoma and Dysidrosis.—Hallepeau says that Robinson has confounded in the description of his hydrocystomas two orders of changes which are distinct: One set of changes is permanent, and thus constitutes veritable cysts to which this denomination can be applied; the other cases are those of dysidrosis limited to the face. Neither the duration of the lesions, nor their desiccation without rupture, nor their annual reproduction, nor their situation exclusively upon the face should make us exclude this diagnosis.—*La Trib. Méd.*, December 25, 1895.

Elimination of Mercury.—Mercury is eliminated by the skin in much larger quantities than has been supposed. After slight friction it is found in greater quantity in the sweat than in the urine. When given internally the elimination in each way is about equal.—Mikoxovitch, *Gaz. Méd. de Liège*, December 12, 1895.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 25, 1896.

THE ADVOCACY OF EXPERT COMMISSIONS.

THE advisability of creating a commission of experts to aid the court and jury in determining the real value of scientific facts, has been so often advocated in these columns that it would hardly seem necessary to refer again to the subject, were it not for the promise of something being done to prove the practical utility of the measure. It is quite likely that a bill will be introduced in the present State legislature covering most if not all of the points involved in previous discussions.

If we mistake not, a committee of the Medical Society of this State is preparing a report to be submitted at the coming meeting favoring such a proposition, with the reasonable probability of its being adopted as the basis for a new law. It is safe to say that the leading members of the legal profession are sufficiently interested in the practical outcome of the project to give it a cordial endorsement. The absurdity of the present method of obtaining expert testimony in our courts is the best argument for a radical change. Even the attorneys whose practice brings them in contact with such cases freely admit that the essential facts are as often perverted in the effort to gain the most for a given side as they are legitimately utilized to obtain strict justice. The jury also, impressed with the belief that a given expert is hired to do the best for a given client, is so chary in accepting the testimony of witnesses for either side that very often the most absurd verdicts are rendered, founded on such facts only as may be presented in exactly opposite scientific aspects. In other words, every effort is made to befog rather than to enlighten a jury, much more depending on the skill of the counsel employed than on the abstract justice of the cause he may advocate. In view of this state of affairs, it is evident that too much responsibility is placed upon a jury, and that the latter must necessarily be incapable of deciding on points concerning which even distinguished expert witnesses so apparently and so radically disagree.

The only reasonable way to overcome such difficulties would be to create a commission of experts, which should be entirely independent and absolutely impartial in its expression of scientific opinion in a given case. In this respect it could act in an advisory capacity to the court and jury as a board of scientific referees on all questions submitted for its direct consideration.

In order to simplify the practical workings of such a commission, a law might be enacted providing for the appointment by the judge of five experts, two of whom should be named by the attorneys on each side. The commission thus formed, be it composed of experts in insanity, medicine, chemistry, surgery, or any other branch of science, could be empowered to examine witnesses, administer oaths, and in every other way supplement the work of the court and jury in gathering facts bearing upon the scientific points at issue, and in thus being the auxiliary and responsible scientific executive of the court itself could advise on all the scientific facts on which the charge to the jury could be based, or from which the jury could obtain additional and necessary information. Some such plan would guarantee more surely and effectually the proper scientific answer to all categorical questions, with the additional and very necessary privilege of impartially and accurately estimating the significance of all qualifying circumstances. The absolute independence of the commission could be thus secured and a proportionate amount of respect be given to its decisions, without in any way militating against the constitutional right of every alleged criminal to a trial by jury. The latter would have not only all its present power of rendering the final and legal verdict, but would gain the additional advantage of an impartial interpretation of leading and material facts by an opportunity for examining through counsel or court the members of the commission as a whole, or, if need be, individually. Any other means to the same end consistent with the requirements of statute could be employed, provided they guaranteed the rendering of a strictly scientific opinion absolutely independent of either side in the case.

SOME NEW LIGHT ON THE FUNCTIONS OF THE STOMACH.

It is coming to be understood more and more that the stomach is not so important an organ, so far as the essential processes of digestion are concerned, as has been generally supposed. Koenig's experiments on animals, in which total extirpation of the stomach was practised, have conclusively shown that the intestines are the real digestive organs, and even in the human being gastric absorption would seem to be quite insignificant, as compared with that of the bowels.

Bunge was the first to point out that the stomach ought to be regarded merely as a reservoir of safety for the rest of the alimentary canal. This view of the lessened physiological importance of the stomach is shared by Dr. Moritz, of Munich, whose observations are referred to in the *Wiener klinische Rundschau* of December 22, 1895.

The proper function of the stomach, according to these recent authors, is to render harmless all those ingesta which might otherwise irritate or damage the bowels. This is accomplished by processes of liquefaction, maceration, disinfection, dilution, and equalizing of the temperature of all substances swallowed.

The fundus of the stomach is entirely different

physiologically from the pylorus. The fundus is principally a receptacle for food. Its digestive capacity is slight. But the pylorus has considerable importance as a motor. It is also stated, in passing, that pure water remains in the stomach for a shorter period of time than any other known fluid.

Everything which produces gastric irritation retards the motive force of the stomach. Food substances of this kind, contrary to what might be expected, remain longer in the stomach than harmless ones.

Vomiting is explained by the newer gastrologists in this way: If the stomach is unable to prepare food properly for intestinal digestion, a reversal of musculo-motor activity takes place and the ingesta are rejected. This explanation strikes us about as forcibly as that of the boy, who said he had to throw up, "because he felt so dreadfully sick at the stomach." Meanwhile we may be permitted to prophesy that, if experimentally inclined clinicians shall continue to supply us with information of such revolutionary character, our text-books of physiology will have to be radically revised.

GASTRIC ACIDITY IN ITS RELATION TO ACIDITY OF THE URINE.

It was Bence Jones who nearly eighty years ago first drew attention to the fact that the reaction of the urine in health underwent certain changes depending on the time which had elapsed since the last meal. Owen, Rees, Nealy, Quincke, and many others have since then amply confirmed Jones' observations. The physiological oscillations in the acidity of the urine are, therefore, at present fairly well understood. But the relation of these variations to digestive disturbances and other diseases has not hitherto received much attention.

Drs. Mathieu and Tréhieux have recently undertaken some researches bearing on the subject, the results of which are published in extenso in the *Archives Générales de Médecine*.

These French observers base their conclusions on four hundred separate examinations of the urine. When it is remembered that they collected the urine of the persons under observation, every hour during the entire afternoon, it must be admitted that their researches were at least painstaking. Without going into wearisome details, the outcome of their studies may be stated in the following propositions:

There is a constant connection between the acidity of the gastric juice and that of the urine.

It is observed that the acidity of the stomach produced either by secretion, by alimentary fermentations, and above all by lactic fermentation, usually causes an increase both in the proportion and in the absolute quantity of acid eliminated by the urine during the process of digestion.

In the normal state, the acidity of the urine is perceptibly lowered in the first few hours after taking food. It becomes progressively greater afterward.

The lowering of the acidity may be preceded by a temporary increase for the first hour after a meal, as

if a certain quantity of acid were produced and then rapidly eliminated.

It happens very often that there is a nearly absolute parallelism between the relative acidity and the absolute quantity of acid thrown off.

This parallelism does not exist when after eating there is a perceptible polyuria. The relative acidity is greater, while the absolute acidity is lowered.

Should anything happen to reduce the amount of gastric acidity notably (lavage of the stomach, vomiting, etc.), this may be noted immediately in a marked diminution of urinary acidity. Under such conditions the urine may become even alkaline.

In hyperchloric dyspepsia the hourly quantity of acid eliminated by the kidneys is considerably higher than in the hypochloric forms of dyspepsia.

The ingestion of milk is followed by a marked increase of acid excreted by the kidneys. This is evidently due to the rapid formation of lactic acid in the stomach. This acid is taken up by the circulation, and through increased diuresis promptly gives rise to increased elimination through the kidneys.

It has not hitherto been found possible to trace graphically the correlation between urinary acidity and the chemical variety of a particular form of dyspepsia.

While the practical results of these French researches cannot be said to be at all important, they will nevertheless stimulate further studies in a domain which modern science is gradually taking away from obscurity and empiricism. Chemistry, bacteriology, pathology, and even surgery are all conspiring to remove the vague term "dyspepsia" from medical nomenclature and assign to diseases of the stomach a place more in keeping with modern ideas of scientific medicine.

THE SANITARY BEARINGS OF TALL BUILDINGS.

THE increasing number of tall buildings in this city has invited a discussion by architects concerning the advisability and safety of such structures. The element of severe and reasonable criticism is so strong that public sentiment is likely to be aroused by the enactment of laws having a prohibitory and restrictive tendency in the required direction. Aside from the greed of landlords in making their investments pay to the uttermost, there is no possible argument in favor of these enormous structures. From a sanitary point of view they are abominations, and an unanswerable insult to the common sense of a plutocratically oppressed people. That the ruthless appropriation of light and air for individual benefit is in itself an invasion of public rights cannot be gainsaid. Worse than all, the narrowest streets are the most invaded, being thus converted into mere alleyways, in which the sun can never shine and the stagnant air of the thoroughfares scarcely be stirred by the strongest wind. In some districts the air of the sidewalk resembles that of a damp cellar, while the causes pertaining to both conditions are strikingly similar. It

is shocking to consider the ultimate effect of a permanent deprivation of sunlight in the lower stories of these buildings, and the unhealthful substitution of artificial illumination. If we add to the insufficient outside ventilation, the extra-damaging elements of the constant atmospheric vitiation indoors, the shutting out of light and air from less pretentious neighboring structures, we can scarcely go further in demonstrating the absolute unfairness of capitalists who look upon the matter only in the light of a profitable business investment.

THE AMBULANCE SEASON.

THE football season is over, and the football player has retired to the classic shades of his 'Varsity, there to give the lumbar enlargement of his spinal cord its necessary rest, and to cause the fallow gray matter of his cerebral convolutions to indulge in needful and healthful exercise. The ambulance season is now on, and the ambulance surgeon is coming to the front in the public notice. His lot is a much less enviable one than that of the football player, though at times it is quite as conspicuous and dramatic. Nothing he does seems to please simultaneously or serially the reporters, the editors, the patients, the superior medical officers, and the managers of his hospital; or, if he adjusts himself eventually to all these environments, the law still remains to be placated.

Nothing could be much more perplexing than the ambulance incident which was much heralded during the past week. According to the accounts in the papers, a man attempted to commit suicide. This is against the law, and hence a criminal complication was at once brought about. The bullet did not produce instant death, and hence his physicians were summoned; they probed the wound, removed the bullet, and put on a bandage. Then the law stepped in, and a policeman summoned an ambulance. The ambulance surgeon, finding a little blood oozing from the wound, very properly tightened the bandage, and this produced a medico-ethical complication, the first doctors alleging that there should have been no interference. The ambulance surgeon having been summoned to bring the case to the hospital, naturally proposed that plan to the family, and this led to exciting domestic protests with much unpleasant verbigeration. Meanwhile the patient incontinently died, leaving the multiple tangles that he had raised by his act to be straightened out as best they might be. Of course, the result was that complaints were made all around, and nobody was satisfied, unless it was the reporters, who always make much good copy out of dissensions. As a matter of fact, it seems that there was nobody to blame, except, perhaps, the man who committed a bungling suicide, and we will not pass judgment upon him.

A Bill has been presented in the House of Representatives, to pay the legal heirs of the late John W. Branhan, assistant surgeon of the U. S. Marine Hospital Service, who died at his post of duty, of yellow fever in 1893, the amount of his pay and an allowance for two years.

News of the Week.

Medical Society of the State of New York.—The ninetieth annual meeting of the society will be held at Jermain Hall, Albany, commencing at 9:15 A.M., January 28, 1896, and continue in session until 1 P.M., January 30th. Attention is called to the change in the time of the meeting, which is one week earlier than has heretofore been customary. Reduced fares can be obtained by applying on starting at the railway station for a certificate, which, on endorsement by the secretary of the Society and the special agent of the Trunk Line Association who will be at the meeting during Tuesday and Wednesday, will entitle its holder to return for one-third fare.

New York County Medical Association.—The meeting of January 20th was devoted to the reading of reports and the election of officers. The treasurer's report showed expenditures of nearly two thousand dollars, and a balance of nearly three hundred. Dr. Bozeman, corresponding and statistical secretary, said the membership had been increased during the year from 1,006 to 1,065. Two members have been expelled. The election resulted as follows: *President*, Dr. Joseph E. Janvrin; *Vice-President*, Dr. H. J. Boldt; *Recording Secretary*, Dr. P. B. Porter; *Corresponding and Statistical Secretary*, Dr. N. G. Bozeman; *Treasurer*, Dr. John Hinton; *Member of Executive Committee*, Dr. John Shrady.

The Dangerous Spitting Nuisance.—Drs. Hermann Biggs and T. Mitchell Prudden, the Health Board pathologists, have prepared a report on the practice of spitting in public places and conveyances, which, in their opinion, is responsible for the dissemination of diseases, such as consumption, pneumonia, influenza, diphtheria, scarlet fever, measles, or whooping-cough. That the practice is merely a habit, and not a necessity, is shown, they say, by the large number of men who are free from it, and the insignificant number of women who are addicted to it. The practice should be abated, the report says, and could be with the assistance of the community. Accompanying the report are resolutions providing that signs should be placed in elevated and surface cars and on the stations of elevated roads, signed by the Health Board, and warning the public against the practice. These signs should also be put in all municipal and federal buildings, and the authorities and elevated roads should be requested to provide spittoons in public places. The resolutions also ask the Manhattan Elevated Railway to give orders to guards to prevent passengers from spitting into the street.

New Health Bill for Mississippi.—The legislature of the State of Mississippi is considering a bill to reorganize the Health Board of the State, which at present consists of twelve members, seven appointed by the governor, one from each congressional district, and five appointed from the State at large on the recommendation of the State Medical Association. The new bill provides that the governor shall appoint five of the seven members upon the recommendation of

the State Medical Association, that their terms of office shall expire with that of the governor making the appointments, and that two members shall not be appointed from the same congressional district. It is said there is every probability of a hard fight over the new bill.

A Very Amusing Discussion is at present in progress between the editor of the New York *MEDICAL RECORD* and the editor of the Philadelphia *Medical News* upon the subject of spelling. In a very modest way we have ventured ourselves on many occasions to animadvert upon the method of spelling adopted by our latter esteemed contemporary, and the following is what the New York *MEDICAL RECORD* has to say on the subject: "Our contemporary, the *Medical News*, has a reprehensible habit of misspelling a good many words and an obstinacy in holding out, even when convicted of error by every other authority, as well as by incontrovertible facts." The discussion has turned in this instance upon the words "uranalysis" and "symphyseotomy." The editor of the *Medical News* objects to each, while the editor of the *RECORD*, in an interesting leading article, justifies their existence etymologically, and points to the fact that the "e" in symphyseotomy is correct, inasmuch as the stem of the word is *φύσε*. It is refreshing to see that at least one of our contemporaries on the other side of the Atlantic has made a stand against the policy of "clipping and changing" which at present disfigures the words in many American medical journals.—*Med. Press*.

The New Library and Hall of the Medical and Chirurgical Faculty of Maryland was formally opened on January 11th. After the opening remarks by the president of the faculty, Dr. Hill, and by Dr. Tiffany and Dr. Ashby, the address of the evening was delivered by Dr. James R. Chadwick, of the Boston Library Association. Dr. Chadwick took for his subject, "Medical Libraries." The exercises were concluded by remarks from Surgeon-General Sternberg and Dr. Robert Fletcher.

Another Doctor in the Senate.—Dr. Godfrey Hunter has been elected senator to represent Kentucky. The United States Senate now contains two physicians, both Republicans, and one a homeopath.

Dr. Grace, the cricketer, has recently lost his brother, who was also a medical man as well as a cricketer. The brother died of apoplexy.

No Verdict in the Brooklyn Vaccination Case.—The jury in the case of Peter Burggref against Health Commissioner Emery and Dr. Frank E. Boyden, for \$5,000 damages for the death of his nine-year-old daughter, which was on trial several days in the Supreme Court, in Brooklyn, has disagreed. The plaintiff alleged that his daughter's death resulted from the compulsory vaccination, which was one of the incidents of the small-pox scare in the spring of 1894.

Obituary Notes.—Dr. Gustave Gartzman, a physician of Newburgh, died January 17th in the Presbyterian Hospital, this city. Dr. Gartzman went to Newburgh about twenty years ago. He was a Prussian, and served in the German army as a surgeon af-

ter graduating in Germany, and also as interne at Bellevue Hospital before going to Newburgh.—Professor K. N. Fenwick, of Kingston, Ontario, died, January 22d, of septic infection from a wound received in operating.

The Bertillon System of Identifying Criminals.—The committee appointed by the New York State Medical Association to confer with a similar committee of the Prison Association of New York, on questions connected with criminology and penology, has recommended what is known as the Bertillon system of identification of prisoners for adoption throughout the State. This system not only renders the identification of prisoners absolute, but is of great scientific value in connection with the study of criminology and anthropology and questions relative thereto.

The Post-Graduate School of Medicine of the District of Columbia.—The bill to incorporate the Post-Graduate School of Medicine was favorably reported by Senator Gallinger, on the 10th inst., and upon his motion was unanimously passed by the Senate. Senator Gallinger is a homeopath physician, and all medical matters arising in the Senate are referred first to him for a medico-senatorial opinion. The senator is greatly interested in medical advancement and gives all such matters his personal attention.

Indiana Board of Health.—The Indiana State Board of Health announced, January 3d, stringent rules in regard to the introduction of infectious diseases into the State, and the notice is accompanied by the statement that the rules will be rigidly enforced. They provide that any common carrier or person bringing any sick person or persons suspected of being sick with small-pox, diphtheria, membranous croup, scarlet fever, or any communicable disease, shall be liable to certain penalties, and the corporations or persons so offending shall also be liable for the charges incident to the care of such sick persons by the local health authorities. It is made the duty of the conductor of a train or the master of a steamboat to notify by telegram the secretary of the Board of Health of the presence of such sick person on his train or vessel, in order that suitable provision may be made for preventing the spread of the disease. All trains and vessels coming to Indiana from any point where communicable diseases obtain are to be subject to inspection by the local health officer, and the charges of such inspection shall be a valid claim against the corporation. The shipment of the body of a person who has died of membranous croup shall not be granted, and no permit shall be issued for the shipment of the body of a person having died of "heart failure" unless the cause of heart failure is stated.

Tuberculous Milk.—Dr. Rowland Godfrey Freeman desires to be reported as having said, at the recent discussion on the milk question before the Section of Public Health, that from the "use of tuberculin it would seem probable that seven per cent. of all cattle in this State are tuberculous."

Chloride of Chromium is said to be a very efficient application in the treatment of cancer.

A New Way to Isolate the Typhoid Bacillus.—According to Professor Brieger, more than seven hundred articles have been written about the typhoid-fever bacillus, in the last few years. Nevertheless, no one has yet discovered a certain method of isolating it until the present time. Such a method has, however, we are told, lately been discovered by Dr. Elsner, assistant physician at Professor Koch's bacteriological institute. After boiling gelatin together with an infusion of potatoes, he adds a quantity of soda and filters and sterilizes the mixture, which is then put into tubes filled with a one-per-cent. solution of iodide of potassium. The tubes are then inoculated with the dejecta, and the gelatin is deposited on glass plates in the usual way. The researches of Dr. Elsner have proved that all bacteria perish in the iodide-of-potassium gelatin except the bacillus of enteric fever and the bacterium coli commune. After twenty-four hours the bacillus of enteric fever is scarcely visible on the gelatin, but the colonies of bacterium coli are already somewhat large at this period. After forty-eight hours the colonies of the enteric-fever bacillus become visible as small clear masses like drops of water, whereas those of the bacterium coli are large and of a dark-brown color. No other bacteria of the dejecta besides the two above named are to be seen. Dr. Elsner has published twelve cases in which he found the bacillus after forty-eight hours in every stage of the illness. The number of the bacilli decreased as soon as the temperature became lower. In one case complicated with thrombosis of both crural veins they were present even after thirty-eight days.

The Genesis of Medical Journalism.—In a review of the present state of the British Medical Association and its journal, the editor refers to "the once popular vogue of the old-established and high-priced weekly medical paper once enjoying the leading position but now, at whatever distance and however nominally, the only approximate rival of the journal." This unkind thrust toward an esteemed contemporary is offset by the contemporary itself, which gives a learned article upon the development of medical journalism. In referring to history on this subject, only three journals are mentioned: *The Gazette of Theophraste Renaudot*, Hufeland's *Journal der Heilkunde*, and the *Lancet*.

The University of Vienna.—The catalogue for the current session shows an attendance in all departments of 5,459. Of this number, 2,213 are in the medical department.

Imported Stimulants.—During the year 1875 there were imported into the United States 1,857,840 bottles of champagne and other sparkling wines; in 1885 the number increased to 2,608,152; and in 1895, just closed, 2,878,140. Enormous as these numbers are, they are quite surpassed by the total for the year 1890, which was 4,753,836.

Anecdote of Dr. Leidy.—Dr. William Hunt, the famous surgeon, tells the following anecdote concerning the venerable doctor: The only instance I ever knew of Dr. Leidy's departure from strict truth was, to a medical man's way of looking at it, a very amus-

ing one. Some years ago he came to my house in quite an enthusiastic mood, and said: "Dr. Hunt, do you know that they are moving the bodies from a very old burying-ground down-town to make way for improvements?" "Yes," I said. "Well," he went on, "two bodies turned into adipocere are there [this is an ammoniacal soap and the bodies are commonly called petrified bodies]. They have been buried for nearly a hundred years: nobody claims them, and they would be rare and instructive additions to our collections." "All right; I shall be delighted." So Leidy went down to secure the prize. When he spoke to the superintendent that gentleman put on airs, talked of violating graves, etc., so the discomfited doctor was about to withdraw. Just then the superintendent touched him significantly on the elbow and said: "I tell you what I do, I give bodies up to the order of relatives." The doctor took the hint, went home, hired a furniture wagon, and armed the driver with an order reading: "Please deliver to bearer the bodies of my grandfather and grandmother." This brought the coveted prizes, and the virtuous caretaker was not forgotten.

Rattlesnake Wine.—Benjamin Gooch in his "Medical and Surgical Observations," published in 1771, gives a summary of different ancient therapeutic methods based on the use of animal poisons. One of his observations relates to a case of severe pain, spasms, etc., of long duration. Gooch says, after speaking of the patient's sufferings: "Not to appear inhuman to so wretched a being, after telling him I could do nothing I sent him a bottle of rattlesnake wine, to take a glass of frequently. This was in the West Indies drank as the highest cordial. Three nights after, the patient walked in. 'Sir,' said he, 'you cannot be so much amazed as I am, nor half so much pleased: I am come to thank you, and if not criminal to worship you.'" Gooch's account of how he learned the virtues of rattlesnake wine is as follows: "A very wealthy old gentleman in the West Indies had long been afflicted with leprosy to a high degree, which was deemed incurable by his physicians. Apparently in a dying state he made his will, leaving a large legacy to a female servant who had lived with him many years. This circumstance being known to the servant, she and her paramour studied and contrived how to make away with him in such a manner as to raise the least suspicion. They put the heads of rattlesnakes into the wine he drank, thinking it would prove an infallible poison; on the contrary, he grew better, and the criminals, imagining the poison was not strong enough, added more snake venom, whereby the gentleman was restored to perfect health. Conscience finally put this servant upon her knees before her master, confessing her crime. Forgiveness was granted, and the old gentleman gave her a sum of money, ordering her to depart and never see him more."

Epileptics in New York State.—At a meeting of the State Board of Charities, held in Albany, January 8th, Dr. Hoyt, Superintendent of State and Alien Poor, made a full report in respect to the number and condition of the dependent epileptics of the State, by which

it appears that the number of such epileptics, exclusive of epileptic insane, is 771, as follows: In county and city poorhouses and almshouses, 427; in institutions for the idiotic and feeble-minded, 152; in all other institutions, 109; in family care, receiving public outdoor poor relief, 83. The Craig Colony, soon to open with accommodations for 200 patients, will be able to receive only about one-fourth of the dependent epileptics of the State, and there can be no further admissions to the institution until additional accommodations are provided.

Discovery of Vaso-Constrictor Nerves of the Heart.

—The announcement of Dr. W. T. Porter's discovery of the vaso-constrictor fibres of the heart, to which former allusion has been made, brings home the fact that the long-cherished dream of making the mammalian heart as accessible to research as any other muscle is now coming true. A quarter-century has passed since the experiments of Bowditch, Merunowicz, Luciani, and Kronecker, in Ludwig's laboratory, led the way for that swarm of investigations on the isolated heart of the frog to which pharmacology and practical medicine owe so much. During these years, more than one investigator, tempted by the harvest that waited on success, has endeavored to isolate the mammalian heart. Martin nearly succeeded, but was obliged to keep the pulmonary circulation intact in order to feed the heart with oxygenated blood. Ludwig, with Pawlow and Stolnikow, greatly improved the details of Martin's method, but was foiled in turn by the difficulty of oxygenating the blood in the absence of the lungs. And yet how simply this great obstacle was finally overcome! Hédon and Gilis, in 1892, received the body of a man guillotined three-quarters of an hour before. They tied the descending aorta and the arteries that spring from the aortic arch and injected into the aorta defibrinated dog's blood. The semilunar valves closed, the blood streamed through the coronary arteries, and the heart recommenced its long interrupted beat. Hédon and Gilis went no further. Their method has since been put into practical use by Langendorff, in Rostock, and in the Harvard Medical School. The isolation of the living mammalian heart has become an easy and certain operation. The discovery of the vasomotor nerves of the heart is as yet the most valuable fruit of this procedure, but it is easy to see that a most enticing field of investigation is now open and that results of the greatest interest are likely to be attained.

The German Surgical Society will celebrate the twenty-fifth anniversary of its foundation, in Berlin, next spring. It has commissioned a Berlin painter, Hans Schadow, to paint portraits of Sir Joseph Lister, Sir James Paget, Professors von Bergmann, König, and Gussenbaur. These will be added to the gallery of celebrated surgeons in the Langenbeck House.

Suburban Sanitaria for Consumptives.—In Berlin a society has been formed for the erection of sanitaria for consumptives. They propose first to put up a number of simple barrack sanitaria in the neighborhood of Berlin.

The Medical Curriculum and Examination in Austria.—A conference upon the course of medical study and medical examinations was held in December with the Minister of Education, and under his chairmanship, by representatives from the various medical centres of Austria. The work of the conference consisted of the consideration of fourteen questions, covering the subjects of discussion. It was decided that the period of study should not be lengthened, but that one year's hospital service in hospitals appointed by the Government should be obligatory upon candidates for medical licenses. The curriculum was divided into two groups of study; the first including the so-called primary natural science subjects, and the second the clinical and medical work proper. In the first group the following subjects are made compulsory: Systematic anatomy, dissection, physiology (with practical work), physics, chemistry, histology, and practical histological work. The subjects recommended, but not obligatory, are biology, history of medicine, and embryology. Admission to the senior studies is only to be permitted after the most rigid examination. In the second group, as obligatory, are included: General and experimental pathology, pharmacology and prescription writing, pathological anatomy and histology, clinical work in internal medicine, surgery, obstetrics and gynecology, ophthalmology, forensic medicine, hygiene with bacteriological investigation, pædiatrics, dermatology, syphilidology, and psychiatry. Obligatory courses are also to be taken in laryngology, otology, vaccination, dentistry, and in surgical manipulation. As not compulsory are recommended: Sanitation, veterinary medicine, epidemiology, toxicology, field surgery, orthopædics, and practice with instruments and dressings. Attendance for twenty-four hours upon weekly lectures or demonstrations is to be required, and the form of examinations is to be left to the board of examiners, who are to satisfy themselves as to the proficiency of the candidate.

New Hospital for the Treatment and Investigation of Tuberculosis.—A society for the establishment of a curative institution for tuberculosis has been organized in Austria, and by private subscriptions has been enabled to purchase land for the realization of its purpose. The site secured is in Alland, in Lower Austria. It is proposed that only cases susceptible to improvement or cure be received, and in the transfer of patients preference is to be given to the two greater Vienna hospitals. Resident physicians are to be appointed, who will be expected to promote the scientific study of tuberculosis and the most approved methods of nursing and treatment. In scientific features, the new hospital is expected to develop a most advanced position.

Death from Pental.—A case is reported of a woman, aged twenty-three, who died under the influence of pental, at the Dental Hospital in London.

St. Mark's Hospital.—Dr. H. N. Vineberg has been appointed attending gynecologist to St. Mark's Hospital, New York.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HONORS AT THE NEW YEAR—CHRISTMAS IN HOSPITAL—CHRISTMAS AND VENEZUELA—CANON WILBERFORCE AGAIN—CENTENARY OF THOMAS WAKLEY—LONDON UNIVERSITY—BRITISH MEDICAL MEETING—DEATHS OF MR. ROUSE AND DR. KIDD—VACANCY IN THE MEDICAL COUNCIL.

LONDON, January 3, 1895.

THE customary list of honors conferred on New Year's day has appeared and contains the names of six doctors. Foremost of these is that of Sir Joseph Fayrer, who receives a baronetcy. He was already K.C.S.I., and held many other distinctions. He has served his country long and well in various offices, and is a great favorite with the profession and a *persona grata* at court. The new honor is hereditary, and if acceptable to him every one will recognize that he deserves it. I am not much in favor of hereditary rank, but the ancient system holds its ground. I think that a life peerage would be a more suitable distinction for individual worth, and a few such would be acquisitions to the upper house. Knighthoods are given to Dr. Willoughby Wade, of Birmingham, Mr. R. M. Craven, of Hull, and Dr. J. A. MacCullagh of Derry. Dr. Nicholls, of Dominica, gets a C.M.G. and Surgeon Lieutenant-Colonel Browne, of Lahore, the C.I.E. Thus three distinctions go to the provinces and two to India and the colonies. No one will grumble at the selection, but many will think a dozen honors might have been given to the profession instead of half that number.

Christmas was kept in most of the hospitals and every effort made by the doctors, nurses, and others to enliven that season for the patients. The children's hospitals and children's wards in the larger institutions were specially cared for, and the little patients must have been as much cheered as was possible.

Speaking of Christmas reminds me of the menacing message of your President, which startled us just before that season of good will to men. The solidarity of the profession here and with you is complete. We regard you as our brethren, and doubt not all your influence is for peace and good will. A curious suggestion has been made here to the effect that the real object of President Cleveland was to render a conflict impossible between the two branches of our race. We may hope at any rate such will be the result, but the method of arriving at it seems to me strange. It reminds me of the old song

"It may have been right to dissemble your love,
But why did you kick me down-stairs?"

Canon Wilberforce seems to have selected the season of good will to renew his attacks on hospitals and the profession, for a letter of his appeared in the *Times* of the 29th ult. in which, instead of apologizing for the falsehood for which he has been rebuked, he pretends to have been hoping that some recognized leader of the honorable medical profession would have authoritatively dissipated the feeling of uneasiness to which he drew attention.

What a state of mind in a canon! He utters a slander, is told it is false, and invites the slandered to prove a negative. His conduct is possibly priestly—it is not Christian.

With the first number of January the *Lancet* enters on its seventy-fourth year and promises a full biography of its founder, Thomas Wakley, for 1896 is the centenary of his birth. The redoubtable editor, coroner, and M.P. was a great reformer, and his works follow him. The early volumes of his journal teem

with his brave denunciations of abuses and fixed determination to reform them.

I spent many an hour when an apprentice in reading them up, and could commend them as instructive and amusing to all would-be medical reformers. I shall follow the biography with the interest of those who knew him and some of his coadjutors.

The office of registrar of the University of London is about to become vacant. The appointment is an enviable one, and was formerly held by Dr. Carpenter, who was succeeded by Dr. Milman. The office brings the holder into contact with numerous scholars and representative men, and carries an emolument of £800 per annum, rising to £1,000.

The invitation of Carlisle for the British Medical Association to meet there next year has been accepted.

The death of Mr. Rouse, senior surgeon to St. George's Hospital, is announced, at the age of sixty-six. He had been in failing health for some time. He was educated at St. George's and has been connected with the hospital throughout his career. He was consulting surgeon to the Royal Westminster Ophthalmic Hospital and held other appointments in the ophthalmic specialty, for he was one of the few hospital surgeons who not only retained his interest in ophthalmology, but practised successfully as an oculist as well as a general surgeon. His writings were confined to the St. George's Hospital Reports and the weekly medical journals.

Dr. George H. Kidd, of Dublin, died last week. A foremost authority in the Irish school, his fame as an obstetrician was such that European and American societies alike delighted to number him among their honorary or corresponding members. Every honor his brethren could confer was his, and when direct representatives in the Medical Council were authorized (1886), he was elected and held the office until his decease last week.

The death of Dr. Kidd renders vacant a seat in the General Medical Council for a direct representative for Ireland. Several candidates are in the field, among them Dr. A. H. Jacob, of Dublin, whose career has been one long course of labor for his professional brethren. Not only in the *Medical Press*, but in the Irish Medical Association and in every public position, he has been for more than a quarter of a century the recognized champion of the medical profession of Ireland.

If his brethren do not now elect him by an overwhelming majority over the nominees of corporations, they will deserve to be abandoned to the representatives of selfish vested interests.

OUR PHILADELPHIA LETTER.

(From our Special Correspondent.)

DOINGS OF THE VARIOUS SOCIETIES.

PHILADELPHIA is eminently a city of medical societies. There are at least six important bodies and a host of minor ones. It has even become the fashion for the students in the medical colleges to form organizations, which they name after favorite professors. It thus comes about that scarcely a night passes without its medical meeting. The communications presented to these various bodies and the discussions elicited range naturally through all degrees of excellence, and there can be no doubt that it would be better if the work thus scattered were brought together. A few thoroughly successful societies would be preferable to a larger number less successful. In the past week, for example, five meetings were held—on Monday by the Academy of Surgery, on Tuesday by the Section of Otology and Laryngology, on Friday by the Section

on General Surgery of the College of Physicians, on Wednesday by the County Medical Society, and on Thursday by the Pathological Society.

At the meeting of the Section of Otolaryngology of the College of Physicians, Dr. B. A. Randall showed an adult male who presented, on otoscopic auscultation, a to-and-fro bruit in the right ear, synchronous with the pulse, and obliterated by pressure on the carotid artery and also in part by Eustachian catheterization. Abnormal swelling or pulsation could be nowhere detected, and the patient complained principally of right-sided tinnitus and impairment of hearing, in conjunction with an absence of exophthalmos and of cardiac lesion, and a denial of syphilis. The condition was believed to depend upon an aneurism of the pharyngeal artery or one of its branches. Dr. E. L. Vansant showed a colored girl, about fourteen years old, who presented a cyst upon the lingual aspect of the epiglottis.

At the meeting of the County Society, Dr. Carl Seiler read a paper on "The Importance of Specific Gravity in Liquids for Topical Medication," in which he inveighed against indefinite instruction upon the part of the physician toward the patient in the preparation and mode of using remedial agents intended for topical application. He made a plea for a standard specific gravity for such liquids, based upon that of a solution of sodium chloride (fifty-eight grains to the pint of distilled water), corresponding closely to the normal saline solution; and contended that much harm resulted from the employment of solutions deviating from this density. Dr. T. S. K. Morton reported a case of "Osteosarcoma Requiring Excision of More than Half of the Inferior Maxilla," in a colored man, twenty-one years of age, and presented the specimen. The operation was entirely successful, and was followed by inconsiderable deformity. Dr. A. O. J. Kelly read a report of a case of "Calculous Pyonephrosis," involving both kidneys, in a woman more than sixty years old, who had presented symptoms referable to this condition for only a relatively short time. The left kidney contained two stones, the right kidney one stone. But little renal structure was left on either side. During life an abnormal swelling had been appreciable upon one side. The case illustrates the danger of surgical intervention with the possible view of removing one of such kidneys without a knowledge of the condition of the other, and also the desirability of some such procedure as ureteral catheterization in the male, either through an opening into the bladder above the pubes or by another route.

At the meeting of the Pathological Society, Dr. W. S. Carter read a report of two cases of sarcoma in one family, and presented the specimens. In the one case, a boy, seven years old, the malignant disease was situated in the structures behind the peritoneum; in the other, a girl, five years of age, the disease involved the sacrum.

The Section on Surgery of the College of Physicians discussed the subject of appendicitis. Dr. D. T. Lainé reported "Cases of Appendicitis Illustrating Some of the Difficulties in Diagnosis Occasionally met with, and Certain Points in the Pathology of the Disease." Dr. Alfred Stengel also made some remarks on the pathology of the disorder. Dr. J. M. Da Costa, who, in his capacity as president of the college, presided over the meeting, pointed out the possibility of confounding with appendicitis attacks of uterine colic in menstruating women, and *vice versa*. Dr. Edward Martin read a paper on "The Operative Treatment of Varicose Veins of the Leg."

Scarcely had Dr. John S. Billings, so well known throughout the world for his bibliographic labors, become domiciled here than he was called to New York to become chief librarian of the Consolidated

Libraries. The recent dinner and testimonial in this city to Dr. Billings are yet fresh in mind, and it was hoped that Philadelphia might hereafter be the field of the activity of this distinguished representative of the medical profession, who has done so much to gain recognition for its literature and to insure its permanent preservation and convenience of access.

Professor Edward G. Conklin, late of the Northwestern University of Illinois, has entered upon his duties as Professor of Comparative Embryology in the medical department of the University of Pennsylvania, in succession to the late Professor John A. Ryder. Dr. Edward C. Kirk has been elected dean of the Dental School of the university. Dr. William Pepper has been elected president, and Dr. D. G. Brinton one of the vice-presidents of the Archeological Society of the university. The total number of students enrolled in all the departments of the university is 2,632, the medical department including the largest number of any single department, 873.

During the month of December, 108 cases were admitted to the Municipal Hospital, including 73 of diphtheria (with 16 deaths—22 per cent.). For the week ending January 4th there has been an increase throughout the city of 35 new cases of diphtheria, and an increase of 5 deaths from the same cause, as compared with the previous week. The total number of deaths for the week was 452, nearly one-third of which, 138, were attributed to "consumption" and "inflammation of the lungs" together. One case of small-pox, at Knoxville, Alleghany County, has been reported to the State Board of Health. The third annual meeting of the Associated Health Authorities of Pennsylvania will be held at Harrisburg, on January 23d and 24th. Papers will be read upon milk purity, water supplies, slaughter houses, pork packing, utilization of offal, the spread of contagious diseases, etc.

The Pennsylvania Hospital—one of the oldest in the country—has in the last few years undergone most radical alteration and extension. A further addition is now contemplated, in the form of a building, fifty by one hundred and thirty-five feet, three stories high, to be devoted to the purposes of a receiving ward and of general clinics. The structure, which will cost \$100,000, is intended as a memorial to a member of the family contributing the funds for its erection.

The Philadelphia medical profession may feel just pride in the poetic abilities of some of its constituents. "The Year-book of the Pegasus," No. 1, which has just been published, contains verses by Drs. S. Solis-Cohen, J. Chalmers Da Costa, J. K. Mitchell, and S. Weir Mitchell. The "Pegasus" is the name assumed by a group of congenially disposed men of literary, artistic, and musical tendencies, mostly engaged in the active pursuits of life, who meet from time to time and entertain one another with the product of their own originality.

SKIN-GRAFTING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of December 7, 1895, p. 800, I noticed an interesting article by Zera J. Lusk, M.D., entitled "A New and Original Method of Obtaining Material for Skin-grafting," in which he employs the epidermis from the surfaces of blisters. That the method is "new and original," as far as Dr. Lusk is concerned, I do not doubt; but, in general, I shall have to claim priority of invention and of publication.

About eighteen months ago I successfully employed, in the Cincinnati Hospital, the epidermis raised by a cantharides blister in grafting an old crural ulcer.

Last March I reported the case in a paper read before the Denver and Arapahoe Medical Society. The paper was subsequently published in *The Denver Medical Times* for May, 1895.

My experiments differed from those of Dr. Lusk in that I used a single large graft to cover the ulcer entirely, as in the Thiersch method, instead of a number of small ones distributed over its surface, according to Reverdin. I also employed the epithelium just as it was removed from the blister, without a preliminary drying. I did not prepare the ulcer by scraping, as Schnitzler and Ewald have shown, and I also have demonstrated to my own satisfaction that this is often unnecessary.

Skin-grafting is thus remarkably simplified by this new and easy process, while its objectionable features are almost entirely removed. There is little or no pain, no hemorrhage whatever, and the patient cannot regard it as a dreaded "surgical operation" unless the local conditions are such as to require a preliminary curetting. The ulcerating surface is first "sterilized" for several days by the application of compresses wet with 1 to 3,000 bichloride solution or with peroxide of hydrogen. A blister of a size and shape to suit the ideas of the surgeon is then raised on some convenient portion of the body, and the layer of epithelium thus obtained is applied to the surface to be grafted. A dry iodoform dressing may be employed. An anæsthetic, often so objectionable, is not required. Patients would be apt to submit to this process when Thiersch grafting would not be permitted. Grafting from one individual to another would also be facilitated.

Owing to my removal from Cincinnati to Denver, it has happened that I have had no opportunity of immediately continuing my experiments, so that I cannot speak with certainty as to the extent to which grafting from blisters may be applied; but, judging from my own experience and that of Dr. Lusk, its applicability will approach that of the Thiersch method.

DENVER, January 6, 1896.

LEONARD FREEMAN, M.D.

TENDON-GRAFTING FOR INFANTILE PARALYSIS—A REPLY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the *MEDICAL RECORD* of January 11, 1896, page 71, I notice a communication from Dr. B. F. Parrish, of Midway, Ky., entitled "Tendon-Grafting, A Question of Priority," in which he seems to think credit should be given to him for having first evolved the above principle.

If after a careful comparison of the two operations the doctor still feels that an injustice has been done him, no one is more willing than I to concede priority. The essential points of difference are as follows:

1. He "cuts away the tendon sheaths."
2. "The opposing tendon surfaces were freshened with the knife and sewed together with catgut suture for a space of an inch or more, and the wound closed."

In my operation:

1. Each tendon sheath was opened longitudinally for one inch.
2. Each tendon was split with a small fascia knife for a distance of one inch, taking off two grafts, the graft from the healthy muscle (extensor proprius pollicis) being left attached at the proximal end of the muscle, while the one taken from the paralyzed (tibialis anticus) muscle was attached at the distal end.
3. The cut surfaces of the two grafts were approximated and sewed together with interrupted sutures of kangaroo tendon.
4. The sheaths of the two tendons were then brought together with a continuous suture of kan-

garoo tendon so as to prevent the newly united grafts becoming adherent to the overlying structures.

5. Adhesion to the newly formed sheath was still further prevented by passive motion, *i.e.*, movements of the great toe every forty-eight hours until union of the grafts had taken place.

After the above comparison of the two operations and technique, let us compare the results. Dr. Parrish did his operation May 15, 1892, more than three and a half years ago, but we have no record of the case, I believe, since December 16, 1892, seven months after the operation, at which date it was reported improved. In conclusion he writes as follows: "I hope, however, to report her case in full at a later date, together with the report of several other cases which I have under observation."

My operation was performed February 14, 1894, but the case was not presented to the New York State Medical Association until October 15, 1895, twenty months after the operation, and not until all apparatus had been left off for five months and the use of the limb restored.

Since my article appeared in the *MEDICAL RECORD*, October 26, 1895, I have to thank Dr. Archibald Church, of Chicago, for having called my attention to an operation performed by Dr. K. Winkelman on January 23, 1894, the case having been presented to a medical society in Germany on February 5th, thirteen days after the operation, but not published until September 18, 1894, in the *Deutsche Zeitschrift für Chirurgie*, vol. xxxix., p. 109.

Dr. Winkelman took a graft from the healthy gastrocnemius and attached it to the paralyzed perineus longus with five interrupted silk sutures. This last reported operation was performed eighteen days before mine, but the case was not shown to a medical society until February 5th, which was only ten days in advance, and was published September 18, 1894, seven months after my operation was performed.

Although Dr. Winkelman undoubtedly can claim priority for having taken part of a healthy muscle and grafted it on to the tendon of one which was paralyzed, the fact that his article was not published until some months afterward allows me to claim originality.

Since Dr. Parrish's rather caustic remarks it is found that Nicoladoni (*Centralblatt für Chirurgie*, p. 700), as far back as April 15, 1881, attached the healthy tendons of the perineal muscles to the tendo Achillis for paralysis of the gastrocnemius and soleus muscles, as he describes it, "in a manner similar to the grafting of trees."

Without taking up any more space in your valuable journal at present, in closing I must call attention to the importance of not only preserving the tendon sheaths, but so far as possible restoring their physiological action. This seems to me one of greatest shortcomings of other operators, and I believe it largely responsible for the limited advance heretofore made in this branch of surgery.

NEW YORK.

SAMUEL E. MILLIKEN, M.D.

A NEW POINT IN THIGH AMPUTATIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In the *MEDICAL RECORD* for December 21, 1895, is printed a report of the meeting of the Section upon Surgery of the New York Academy for December 9th. In this I am made to say: "Dr. Dawbarn said that in all hip-joint amputations he hamstringed his patients, in order to prevent retraction of the muscles and their unequal length and pocketing after division. This saved time spent in suturing them on a common level."

As a rule the *MEDICAL RECORD*'s reports are accu-

rate, but this statement italicized is quite misleading. It is in fact just the reverse of what I said.

Upon the occasion in question, the section cards announced a paper by Dr. F. T. Brown; subject, "Two Thigh Amputations by a New Method." Accordingly, a discussion of new methods herein was in order. And this present letter is an amplification of what I then said.

So far as my recollection goes, the plan I am about to describe is new in print. I have taught it for ten years at the Polyclinic School, however. So simple, so self-evidently a good thing is it, that the wonder is that every surgical text-book does not contain it; and I quite expect that some one will now come forward and state where it may be found published.

I refer to "hamstringing" the patient just prior to any thigh amputation.

The technique is as follows: The thigh being elevated and "milked" as usual, and the leg held extended on the thigh, thereby causing the hamstring tendons to stand out tensely, the surgeon divides these, on both sides, with two bold strokes of the knife. No vessel of much size is cut in so doing; still, an assistant instantly prevents bleeding by thrusting his thumbs into these wounds.

Of course, this has only taken a few seconds to do; and now (not before) the customary Esmarch bandage or stout rubber tube is applied above the point at which it is decided to amputate. Then the operation proceeds as usual, bloodlessly.

The reason for advocating the hamstringing is simple, but involves a brief statement of well-known anatomical facts. None of the hamstring muscles (save a part of one, the biceps) has any attachment to the thigh bone, but all arise from the pelvis and are inserted below the knee. These are the sartorius, gracilis, semi-tendinosus, semi-membranosus; also the biceps, except as aforesaid.

Consequently, when these muscles are cut across in a thigh amputation, nothing prevents their retraction for a long distance.

All the other thigh muscles, such as the vastus externus, vastus internus, crureus, and the adductors, are attached to the thigh bone, and for considerable distances. Consequently, when these latter muscles are cut across in a thigh amputation they cannot retract far.

Every surgeon knows, practically, that the thigh muscles do retract to very unequal distances in the stump. It was for this reason that *suture en étage* was devised—sewing together the muscles in the interior of a stump, tier after tier, to make a comparatively solid muscular end, instead of one full of holes and so-called "dead spaces."

Regarding this matter of differing length of retraction of different muscles, Treves states ("Operative Surgery," vol. i., p. 271): "All muscles, of course, contract on division, but the extent of that contraction is subject to remarkable variations.

"Those muscles retract most which are quite free between their points of origin and insertion, and which are provided with long fibres; such as the sartorius, gracilis, and biceps humeri.

"These muscles may lose, according to Farabeuf, as much as four-fifths of their length on division.

"Those muscles contract least which are provided with short fibres (as illustrated by the penniform and bipenniform muscles), which are connected with bone at the seat of the division," etc.

So much for the anatomical explanation. The application is plain. If we "hamstring" our patient, those muscles which regularly retract furthest when cut are the ones divided, and they at once shorten up; and when a little later we proceed to amputate through the thigh, we shall find that our stump end

will be quite a smooth one, for all its muscles will then retract about equally.

Of course, the Esmarch bandage, or tube, should be applied only after the hamstringing; otherwise it would interfere with the purpose for which this cutting is done.

Before a thigh amputation one may, of course, also divide the rectus femoris tendon of insertion into the patella. This would be in line with what I have been advising, as this muscle has no direct attachment to the thigh bone. However, it does not retract so far as do the hamstring tendons; probably because of its short, bipenniform fibres, as suggested above (Treves). Hence the gain in smoothness of the stump would be but slight.

It will be plain that the same principle may properly be applied in certain other amputations. For instance, division of the tendo Achillis just prior to leg amputation, will permit the gastrocnemius to do most of its shortening at that time. The same idea holds good in division of the biceps humeri tendon before amputation through the upper arm.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 6, 1895.

ANDREW H. SMITH, M.D., PRESIDENT, IN THE CHAIR.

A Case Showing the Permanent Benefit from an Operation on the Ear for Deafness and Tinnitus Arising from Progressive Catarrhal Inflammation of the Middle Ear.—DR. SAMUEL SEXTON related the following case: The patient is a domestic. She came to me in November, 1887. She was then thirty-two years of age, and stated that she had been obliged to give up several situations on account of her deafness.

She also suffered greatly from tinnitus in both ears, which often prevented her from sleeping well at night. She could hear an ordinary conversational tone of voice only in the right ear at ten inches. The hearing of the left ear was only slightly impaired, but the noises in her ears made it difficult to hear in the better ear. The drumhead and malleus were excised on the right side in November, 1887, and she was presented to the Practitioners' Society at its December meeting that year. The result of the operation was an improvement of hearing in the right ear from ten inches for ordinary voice to two and a half feet, and the almost entire absence of tinnitus.

The patient has remained in service ever since, but of late has found the deafness to interfere again with her work. She, therefore, came to me again in November, 1895, when it was found that the good result obtained by the operation on the right ear has remained, but the hearing of the left ear, which had been very good when she first came in 1887, had become so bad that she now hears only a very little unless words are spoken directly into the ear. The severe tinnitus, however, has not returned. There is now a good-sized and permanent opening in the drumhead of the right ear, and the mucous membrane of the drum has become transformed into dermoid or cicatricial tissue, which, of course, prevents further sclerosis taking place. In the left drum the catarrhal inflammation has gradually progressed with consequent increase of deafness.

I know of no other treatment whereby such an im-

provement of hearing can be brought about in such cases, and the progress of the disease arrested.

Extensive Operations for Malignant Disease.—

DR. CHARLES MCBURNEY presented two patients as a basis for some remarks on the necessity for thorough removal in malignant disease. The first was a woman, about sixty years of age, with tumor, present two years, involving a considerable portion of the right breast and extending to the axillary lymphatics. On the eleventh of last May he performed the operation recently and almost simultaneously described by Dr. Halsted, of Baltimore, and Dr. Willy Meyer, of New York. It was in effect an elaboration and perfection of the operation originally suggested by Volkmann. The design of the operation was to remove the disease in loco and along with it the channels through which it was likely to be transmitted to other parts of the body. The plan of the operation was to remove not only the entire breast, but also with it, in one mass, all of the pectoralis major and minor muscles except in some cases a part of the clavicular portion of the major muscle; everything in the axilla except the posterior nerves; also all the lymphatic glands in the supraclavicular region. In this way the usual channels of distribution of the disease were removed, although it was possible, of course, for it already to have reached the thorax or inaccessible parts, in which event a cure could not be effected. But the results had been extremely satisfactory, especially in fifty cases reported by Dr. Halsted one to five years subsequent to the operation. In only three had there been recurrence in the scar or its immediate neighborhood. Of course, in some, disease had already existed at a distance and they died subsequently. None died from the operation.

The dissection began two inches above the clavicle, taking everything excepting skin and a thin layer of fat away to below the breast, to near the median line, and outward in the axilla, including both pectoral muscles. Sometimes a considerable open surface was left, and cicatrization was hastened by skin grafts. The operation sounded like a more formidable one than it really was. Dr. Halsted's patients and his own twelve or more had done remarkably well. One who had never seen it performed would expect to find considerable limitation of motion, but the patient presented illustrated the rule of preservation of free motion. She was able voluntarily to place the hand on the head, on the other shoulder, and behind the back, and in doing so to exert plenty of power—all that was required for the enjoyment of life. The extreme upper clavicular portion of the pectoralis major was not removed. The other motions peculiar to this muscle were made by the anterior part of the deltoid. The patient had been discharged thirty-four days after the operation, which, under the circumstances, was not a long stay in hospital.

Dr. McBurney thought the operation had a great deal to recommend it, and his feeling was based on his own experience and reported statistics which were absolutely reliable, that carcinoma of the breast should never be operated upon in a less thorough manner.

DR. KINNICUTT inquired why it was recommended to leave the supraclavicular glands in certain cases.

DR. MCBURNEY replied that where the tumor was small and but a single enlarged gland could be felt in the lower axillary space, examination had shown that the supra-clavicular glands were not diseased, and therefore did not require removal. But where there was any doubt on the point they should be removed. One should never stop at the edge of the disease.

Carcinoma of Tongue: Kocher's Operation.—The second patient presented by Dr. McBurney was a man, about fifty years of age, operated upon for carcinoma of the tongue September 5, 1895. There had been

much pain, constant salivation, and difficult deglutition for five months, and when he came under Dr. McBurney's observation there was a large tumor of the tongue, occupying fully two-thirds of its area, extending down to its base, and involving the pillar of the fauces on the right side. As in the case of carcinoma of the breast, a very thorough operation was undertaken for its removal. It was known as Kocher's operation, and was one of the most scientific in the whole range of surgery for carcinoma. Indeed, it was the only one which permitted thorough work in extirpating the tongue for cancerous tumor. The tongue was reached from the neck, the only situation at which it could be attacked without damage to important parts and disfiguration.

The ease and safety of the operation depended upon two or three things. In the first place it should always be preceded by immediate tracheotomy, which disposed of difficulty with respiration and anaesthesia. The tube was inserted between the cricoid and thyroid cartilages, and through it ether was administered. In his case the left lingual artery was first tied. On the right side he made an incision passing along the inner border of the digastric muscle down to the hyoid bone, then down parallel with it, and then upward along the sterno-cleido-mastoid almost to the ear. This triangular flap, including skin and superficial fascia only, was dissected from the submaxillary region up to the face. The submaxillary triangle was then excavated, the tissues removed being the submaxillary gland, the lymphatics, and all the tissues down to the muscular floor of the submaxillary space. If the disease had already involved this region the dissection should be carried still farther toward the clavicle. This could be done without difficulty or danger. The flap having been turned up, the submaxillary region cleaned out, and the vessels tied, one was ready to enter the cavity of the mouth. Before doing this, a large sponge was thrust into the mouth and pushed down to shut off the laryngeal orifice. It was easy, with the finger in the mouth, to cut the mucous membrane and attachments along the jaw, and through this opening to pull down the tongue by means of a silk suture passed through its tip. The tongue was then released from the floor of the mouth as far as was required, going down to the hyoid bone. The arteries having been tied, there was no hemorrhage. Through the same wound the pillar of the fauces, one or both sides, could be taken out without any trouble. One might expect considerable difficulty with the wound, but cicatrization was very satisfactory; the whole scar drew up under the jaw, and there was little or no deformity. His patient's condition was in marked contrast with what it had been before the operation, when he was pallid, greatly emaciated, suffering from pain, and saliva constantly running out of the mouth, and inability to swallow even fluids. He had since gained largely in weight, was not troubled with his saliva, pain had disappeared, and could swallow easily with a full mouth, the last drops giving slight trouble.

In order to obtain perfect results, it was necessary to feed these patients per rectum a number of days. Then while the wound was healing, the food was introduced through a stomach tube. This patient was able to make himself understood in spite of the fact that all the tongue had been removed.

The very satisfactory results obtained from these more thorough operations for carcinoma furnished an argument of irresistible force against the lesser operations which were at first so attractive to the patient but so absolutely unsatisfactory to the surgeon and patient in the end. For instance, what could be more unscientific, because out of proportion to the disease and danger of extension, than Whitehead's operation which was being performed so frequently in England?

No provision was made by the Whitehead operation against secondary formations, either those that were present or likely to develop. It seemed to Dr. McBurney that no operation should be undertaken for malignant disease of the tongue without thorough removal of adjacent lymphatics. Anything less was a deception, not only to the patient but to the surgeon himself, and worked an absolute injury to the cause of surgery. So in tumors of the breast an operation of small grade upon a small tumor of the breast was a fraud. There was no propriety, no matter how small the carcinoma of the breast, in taking out the breast alone. No matter how small the carcinoma, the operation should never be much less than the one he had described. Laboratory examination had shown that, however small the tumor, the disease could be found at a considerable distance. Since he had made it a rule to have the axillary glands examined in every case, he had not seen an instance in which one or more of them was not involved, however small the mammary tumor, or however far from the axillary region. That fact alone, in view of the extent of his experience, was sufficient to quite justify his statement that a small operation on the breast was a fraud certain to be rapidly followed by recurrence of disease.

He said Dr. Halsted had furnished an excellent contribution to the subject of small tumors of the breast by showing that the disease was already present in the fascia of the pectoral muscles, even when the tumors were extraordinarily small.

A Case of Filaria.—The President, DR. ANDREW H. SMITH, presented a patient with the following history: An Englishman, aged twenty-eight, admitted to the hospital November 26, 1895. Family history negative. Formerly he had been a hard drinker, lately only a moderate one. About four years ago, while in South America, he began to suffer from severe paroxysms of chills and fever, at first occurring about every fourth week, oftener after a year or two. They came on without warning, the chill lasting one or two hours, followed by high fever of two or three days' duration. He said his temperature often reached 105° F. After the fever there was sweating. During the paroxysm he had a great deal of pain in the stomach, nausea, and sometimes vomiting. Three years and a half ago the left leg began to swell, increasing in proportion to the frequency and severity of the paroxysms. He left South America several times, visiting Bermuda and other places with the hope of getting rid of these attacks. No kind of treatment seemed to benefit him. A year later the same phenomena which had appeared in the left leg began to show themselves in the right one, having been preceded by swellings in the groin and red inflammatory streaks down the thigh. Having lost strength and about fifty pounds in weight, he followed the advice of his doctor and came to New York, where he remained during his first visit about six months. He had one attack two weeks after his arrival and three or four others, but they were not so severe. Not being benefited by treatment, he went to Canada, but the paroxysms continued to come on, although at longer intervals. The left leg became very painful. A surgeon introduced an aspirating needle deep into the calf and withdrew pus. An incision was then made in this locality and the patient stated that about three pints of pus escaped. The scrotum, which had begun to swell about the same time as the legs, was also incised in front and behind, and a small amount of pus was found. He was laid up about six weeks after these operations, and at the end of that time the swelling of the leg and scrotum had markedly subsided. He then left Canada and came to New York. The left leg began to swell again, the paroxysms recurred about once in four months, but in milder form. On resting a few days the swelling of the leg subsided

considerably, but it prevented him from going about much and caused much pain on walking. The urine was normal in amount except during the paroxysms, when it was markedly diminished, and afterward contained sediment and was dark in color.

The hospital notes, taken since November 24th, were as follows: On that day he had a severe chill, followed by fever and sweating; severe headache, nausea, and vomiting. Two days later, on admission, the temperature was 103.8° F., pulse 96, respiration 28, urine negative. A week later the urine contained about five per cent. of albumin and a few casts. The area of dulness over the spleen was increased, extending on deep inspiration about half an inch below the ribs.

The left leg was swollen about twice the size of the right, there was considerable tenderness along the tibia, the old cicatrices were present, the scrotum was much swollen.

About two days after admission his blood was examined at night, after the paroxysm had subsided. It was full of thread-like material, of different lengths and sizes—filaria. This continued to be found until two nights ago, when it was absent. None of the filaria showed movements. Photographs were taken. Dr. Smith said the history of the case corresponded with that of others of *filaria sanguinis hominis*. The filaria were filament-like bodies, about the diameter of a blood corpuscle and averaging about one seventy-fifth of an inch in length.

Discussion of the cases being in order, DR. BRYANT inquired of Dr. Sexton what was likely to be the final result on the hearing in his case.

DR. SEXTON thought the hearing would remain good. Ten years having elapsed, it was not likely to diminish except so far as it might be influenced by old age, as in other persons. Of course the maintenance of an opening in the drumhead was important, but that was a simple matter.

DR. BEVERLEY ROBINSON inquired what had been the nature of the operation in this case, and Dr. Sexton replied that it was removal of the drumhead and malleolus. Dr. Robinson then mentioned the case of a patient who had visited many eminent otologists in this country and abroad, and as no improvement had been experienced he submitted to this operation at the hands of a distinguished otologist here, with Dr. Robinson's consent. Dr. Robinson regretted having had the operation done, for the patient had told him that his subjective sensations were more distressing than they had been previously. Of course one case proved little, yet he thought, even when nothing remained to be done except this operation, the patient should be informed beforehand that it might not result in improvement.

DR. SEXTON inquired what were the symptoms which had been exaggerated after the operation.

DR. ROBINSON replied that the human voice had become more unpleasant to him.

DR. SEXTON said it was easy to understand how the patient's condition could be rendered worse by a bungling operation, but it was not so plain how this result could follow an operation skilfully performed. He had known patients not to be benefited, but not many. When Dr. McBurney had described a certain treatment for cases of cancer as fraudulent it had set him to thinking that the treatment which had been in vogue many years in these ear cases might be designated by a similar term, although he would not have used it had he not been encouraged by the example of Dr. McBurney. Many of these cases which had come to him had for years been floating around from one doctor to another, having their ears inflated and their throats treated, without the slightest benefit. Until we recognized the fact that the only way to arrest a progressive disease of this kind was such an operation

as had been described, we would not be doing full justice to our patients.

DR. ROBINSON wished to say further, that he had given considerable attention to this subject and had tried to follow up the opinions of others, and the impression which he had received was that, while the majority of otologists undoubtedly were of opinion that in many instances old suppurative trouble of the middle ear was benefited by taking out the ossicles, yet there was a difference of opinion as to the propriety of removing the drumhead and ossicles in the form of catarrh spoken of to-night. That was a very different matter. We might not improve the hearing and we might render the patient's appreciation of sound distressing, much more distressing than the tinnitus which had previously existed and which could be relieved largely by judicious medication.

DR. GEO. F. SHRADY asked Dr. McBurney, in connection with his case of carcinoma of the breast, how many such he had had without recurrence after three or four years, operated upon by the older methods.

DR. MCBURNEY replied that in hospital practice one lost sight of most of these cases. He could not just then recall a case in which the breast was removed by older methods for tumor, no matter how small, and which had remained perfectly well since. He had seen plenty of recurrences.

DR. SHRADY thought recurrence was the rule. He had, however, followed one case for eleven years after removing the breast and cleaning out the axilla. There was no recurrence, and after death examination revealed no cancerous disease. In another case, operated upon three years ago, there had been no recurrence.

Dr. Shrady thought there was no argument against this more radical operation described by Dr. McBurney, but he had not yet had any personal experience with it. It had always been his habit to clean the pectoral muscle, and sometimes to remove more or less of it. In one case three years ago he took nearly the whole of the pectoralis major away and a portion of the pectoralis minor, and also cleaned out the supraclavicular region, but in that instance recurrence took place, showing that the operation was not even radical enough. Of course the rule to operate wide of the disease was one well recognized in general surgery, and he believed that every surgeon cleaned out the axilla even in the old method of operating. The result of the later more radical operation as to motion of the arm was very satisfactory, although he would not have expected it.

DR. JOSEPH D. BRYANT said he had given the subject of cancer careful consideration during the last four or five years, and he was very glad to witness to-night the results of the later operation described by Dr. McBurney. He wished to state most emphatically that he regarded it as the proper method of procedure. To his mind there was no greater evil existing in the profession of this country to-day than the disposition of some to regard a tumor of the breast as of little consequence simply because it happened to be small when first observed, or because there seemed to be no accompanying enlargement of the glands in the axilla. In this connection he could not do better than mention four cases which had come under his observation in the last three months. One was a case of tumor the size of a hen's egg in the lower portion of the breast. He was asked to remove it, the statement having been made that there was no enlargement of the glands in the axilla, nor could he feel any himself, but not being satisfied with this form of examination he made a free incision in the axilla and then had no difficulty in finding quite a number of enlarged glands which he proceeded to remove. The mammary tumor in this case had been present only three months. The next case was one of tumor a little larger than a walnut in the

upper part of the breast. No glands could be felt in the axilla, either by manipulation or by incision, but being convinced that it was a malignant tumor he removed it and entered the axilla, and then, being able to get the tissues between his thumb and finger, enlarged glands could be felt.

Regarding the order in which the glands enlarged, they did not enlarge one after another according to their distance in the lymphatic chain from the tumor. They enlarged irregularly. He had found enlarged glands in the apex of the axilla when scarcely any change could be found along the border of the pectoralis major.

A case of malignant growth of the breast operated upon at St. Vincent's three years ago had demonstrated another point to his satisfaction, namely, that the glands in this disease might be degenerated without showing increase in size. These facts emphasized the point made by Dr. McBurney, that the only course to pursue was to perform a thoroughly radical operation.

DR. PEABODY, who had come in after Dr. McBurney's patient had been shown, asked whether surgeons could give assurance of successful result by any operation.

DR. ROBINSON said there were small tumors of the breast of whose nature the physician sometimes felt himself ignorant and he referred the patient to a surgeon, who also might be in doubt. He would ask, therefore, whether all doubtful tumors of the breast should be removed. A case in point was that of a lady who had a tumor removed from the breast while abroad, the nature of the tumor not having been revealed to her. She came to him subsequently with a small tumor of the breast, and owing to the previous history he was more than ordinarily suspicious and referred her to a surgeon. The surgeon was in doubt, introduced an aspirating needle, withdrew some fluid, and concluded that it was cystic, not malignant, and did not remove it. This was two years ago, and to-day there is no disease of the breast. Should all doubtful tumors be removed, no matter how small?

Recurrence or New Growth?—DR. CLEMENT CLEVELAND mentioned the fact that if there were freedom for five or six years after removal of a malignant growth it was thought there would be little likelihood of recurrence. Yet within two years he had seen an insane woman in the Bloomingdale Asylum, ninety-two years of age, who had had the breast removed thirty-two years before and who was at the time he saw her suffering from cancer in the old scar and died of the disease three months later. Was it a recurrence, or was it a new growth?

DR. MCBURNEY thought it would be acknowledged almost universally by surgeons that Dr. Cleveland's case was one of cure and that new disease developed. It was generally recognized that a case which had gone five years without recurrence could be fairly regarded as cured, but there was no reason why a patient who had had cancer once should not have it again, no more than that a patient who had been cured of inguinal hernia should not have it on the other side.

Dr. McBurney repeated that this operation for carcinoma of the breast was not a blind one done with a view of going as far distant around the tumor as possible; it was a scientific operation, elaborated by many years of anatomical and surgical study. As to freedom from recurrence, the difference between the older and the later method of operating was that by the former the best result was six per cent. free after a year and a half; by the latter, sixty per cent. free after five years.

He believed that most surgeons were agreed on the point that where there were no contraindications it was best to take out all small tumors of the breast. An exploratory incision was the grand resource in cases of

doubt. An expert pathologist could pass upon the nature of the tumor at once, and the operation could be completed in accord with his report. A good general rule was to get rid of all abnormal growths.

DR. F. P. KINNICUTT, discussing Dr. Smith's case of filaria which he had also seen in the hospitals, replied to an inquiry that inflammations, œdemas, and suppurations were common in this affection. The parasites were discharged from the pouch of the adult female worm in great numbers into the blood and lymph channels, and as long as this occurred only after they had reached maturity they were supposed not to block up either the small lymph or small blood vessels, for their diameter was about that of a red blood corpuscle. But the immature parasite was coiled up, forming a ball many times the diameter of a red blood cell, and if it were aborted into the blood-vessels in this state it would be likely to cause obstruction producing œdema, suppuration, etc. The only unusual circumstance about the case shown by the president was, it seemed, that all the parasites were found dead. This had sometimes been observed before, but usually the parasites were full of life, and wriggled vigorously about on the slide of the microscope. In the adult female the vaginal pouch extended almost from the mouth to the tail, and out of the opening just below the head enormous numbers of the embryo were discharged.

DR. W. GILMAN THOMPSON showed a photograph given him by Dr. Byrom, taken about six years ago, of the parasite in motion, being the best on record. It was of interest also from the fact that the worm was kept alive in undiminished vigor for twenty-four hours outside the human body. It was a marvel to see it in the midst of a lot of blood corpuscles gathered up in its coil and pushed aside with great vigor. The diameter of the worm was somewhat greater than that of a red corpuscle, and the diameter of the latter was even greater than that of some of the capillaries so that they had to double up in order to get through them. Further, the length of the worm was greater than that of the capillaries. It must, therefore, do a great deal of twisting in order to get through from the arterial to the venous circulation.

DR. PEABODY recalled a case in which the man suffered from difficult micturition from chylous urine and the passage of what appeared like partial casts of the urethra, and Dr. Kinnicutt stated that the patient presented this evening had suffered in a similar way. Manson's writings having been referred to, Dr. Peabody said the explanation given by that authority was that the mosquito drank of the blood of the infected host, alighted upon water, there died and the worm, undergoing transformation and becoming mature, infected the water. It was through drinking this water that persons became infected. Monkeys were wiser, refusing to drink it.

The Bicycle Doctor.—An enterprising Chicago cyclist has distributed the following: "Bicycle surgery. Acute and chronic cases treated with assurance of success. Languid tires restored to health and vigor. Tires blown up without pain. Wind free. We understand the anatomy, physiology, and hygiene of wheels and give homeopathic or allopathic treatment as individual cases require. Sure cure guaranteed. Testimonials: 'My wheel had three ribs fractured and you cured it in one treatment.' 'My tires were suffering with a case of acute aneurism, which had been pronounced fatal by other bicycle doctors, but you cured the disorder and I did not lose a day of my tour.' 'I was troubled with varicose tires, involving frequent ruptures and incontinence of wind. You cured me.' Thousands of testimonials like the above sent on application."

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 16, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Empyema.—The meeting was under the direction of the Pædiatric Section, Dr. Floyd M. Crandall, Chairman. The topic for discussion was empyema, on which three papers were read.

The Bacteriology of Empyema in Children.—DR. HENRY KOPLIK read this paper. In relation to the bacteriology, there were four main groups of cases of empyema in children. By far the largest group was that of meta-pneumonic pleurisy, comprising probably two-thirds of all cases occurring in children and in which was present the diplococcus pneumoniae, although there might also be present streptococci. Here the empyema followed pneumonia, but sometimes the lung process was so slight as scarcely to attract attention. The next group was that in which streptococci were the cause. Some of these cases were benign, others developed putrid pus and probably some specially virulent micro-organism was the cause. A third group was due to the tubercle bacillus. In some instances this bacillus had not been found in the exudate, while streptococci were present, but inoculations producing tuberculosis in animals proved the real nature of the pleurisy. Then from time to time there had been published cases in which other bacteria, as that of typhoid fever, had given rise to empyema.

In regard to the streptococci group, the infection could start from various localities, as retropharyngeal abscess, osteomyelitis, etc. In adults the tuberculous group was much greater than in children, the tubercle bacilli having been found in at least twenty-five per cent. of the cases, and probably being the cause in over sixty-per cent., while in children the meta-pneumonic group and other forms than tuberculous comprised most of the cases.

The Diagnosis and Peculiarities of Pyothorax in Children.—DR. AUGUST CAILLÉ thought physical diagnosis as applied to the thorax gave such positive evidence of abnormal conditions that it would seem impossible to overlook general or localized pleuritic exudate, yet it was of daily occurrence that mistakes were being made and wrong conclusions arrived at through faulty interpretation of physical signs. After some preliminary remarks upon the bacteriology, frequency, origin, and other points, the author passed to the subject proper of his paper, diagnosis and peculiarities of pyothorax in children. Purulent fluids, as distinguished from serous fluid, in the chest could be determined by the aspirating needle alone. The presence of peptones in the urine in pyothorax was by no means a distinguishing feature, as it had been observed in intestinal ulceration, the third stage of pneumonia, syphilis, etc. One should bear in mind the possibility of a hydrothorax being due to disease of the heart or kidneys. A severe case of pleurisy, with irregular temperature curve, pain, cough, and dyspnoea due to effusion, would be readily recognized by a careful observer. The change of a simple pneumonia into a pleuropneumonia was not difficult to recognize. Children with simple pneumonia cried readily, without much evidence of pain, while pleuropneumonia caused them to cry with pain on handling, diaphragmatic respiration stopped, and the entire thorax was lifted with each inspiration.

Puzzling cases were those in which the question came up whether the patient was suffering from an unresolved pneumonia, dulness still persisting, or pleurisy with effusion. In both there might be absence of expectoration, irregular temperature curve, pain, cough, dyspnoea, and the physical sign dulness. Aside from aspiration, our judgment must rest upon

inspection, palpation, auscultation, and percussion. Lateral curvature of the spine, lack of movement of the affected side, bulging of that side, bulging or retraction of the intercostal spaces on inspiration, displacement of heart, dyspnoea, cutaneous oedema, enlargement of cutaneous veins, pallor of skin—all these signs might be present and most of them could be absent in empyema. Moderate dyspnoea on exertion was usually noticeable; occasionally he had observed concavity instead of convexity on the affected side. Poor appetite was usual. In pyothorax displaced heart's action was not commonly seen. Cutaneous oedema and enlarged veins were occasional; lateral curvature might be present in old cases. Fever might be absent in pyothorax, as he had witnessed in a few cases. Bulging of the intercostal spaces was generally absent in the presence of small exudate, retracted thorax, or small intercostal spaces. Vocal fremitus was usually absent over the fluid, but it could not be relied upon to distinguish between serous fluid and pus. Make the child cry and compare the two sides. In auscultation absence of respiratory sound over fluid was a classical sign, but there were exceptions to the rule. A thin layer of fluid in the lower part would not obscure the breathing sound. Tubal breathing might be transmitted from the adjacent or underlying compressed lung. Friction sounds could be heard before effusion and after its absorption. Amphoric, cracked-pot, and other sounds, usually absent, were sometimes heard. Rachitic flat, or deformed chest might give apparent flatness on percussion and mislead the examiner to diagnose fluid. Consolidated lung, thick fibrinous exudate, and tumors must be excluded as causes of the flatness. Marked resistance to the finger on percussion was of great value as a diagnostic sign of fluid. Marked displacement of neighboring organs was rare in children. Alteration in height of fluid by change of position was an indistinct sign in children.

Bearing in mind the variability in the physical and rational signs of fluid in the thorax, it became evident that the etiology was important in order to interpret the physical conditions present in doubtful cases. When fluid was suspected, its presence or absence could be best proved by use of the aspirating needle, and this was the only way to tell its character. Some cases of difficult or erroneous diagnosis were cited. Empyema in children usually ended in complete recovery if operated upon early. Even in desperate cases free incision should be made at once.

The Treatment of Empyema in Children.—DR. JOSEPH E. WINTERS thought the natural history of empyema offered a clear indication of what the treatment should be. There was no doubt of the disastrous issue of nearly all cases when left to themselves, and when cure took place it was by discharge and drainage externally or through a bronchus. Treatment should consist in removing the pus by external incision, preventing reaccumulation of fluid, securing complete expansion of lung, leaving behind no deformity. Dr. Winters held that emptying the chest cavity of pus after incision was not by gravity, but by expansion of the lung and pushing up by the diaphragm. We should try to maintain full expansion of the lung, and if this did not take place the prognosis as to ultimate recovery was doubtful. It had been said that the diminished mortality of recent years was due to improved methods of treatment, but Dr. Winters attributed it to earlier diagnosis and prompt incision.

Statistics were quoted to show the greater safety of incision compared with excision of part of a rib in empyema in children. The incision should be at least two inches above the base of the fluid, and at least two inches long. The aspirating needle could be left in after finding pus, as a guide for the

scalpel. Chloroform was preferable to ether. The patient should not be fully anesthetized, as it was desirable he should cough in order to expel the pus and exudate forcibly. Some considered irrigation dangerous, but Dr. Winters had not found it so, and had even seen stimulation follow when only hot water was used, 125° F. to 130° F., the patient lying at the edge of the bed and resting on the affected side. Give a teaspoonful of whiskey to produce coughing as well as stimulation. The main factors which lead to obliteration of the cavity were: 1, expansion of the lung; 2, sinking of the diaphragm; 3, falling in of the chest. The latter was not desired until there had been complete expansion of the lung. Later it was proper to resort to exercises for the expansion of the lung, such as blowing on wind instruments.

Pleurisy and Chronic Pneumonia.—DR. A. JACOB opened the discussion under protest. He fully agreed with a remark of Dr. Winters that empyema was now less frequently wrongly diagnosticated as chronic pneumonia than formerly. But he understood one of the speakers to say that when fever lasted a number of weeks and there was dulness it signified pleurisy. This was not necessarily so, for he had seen quite a number of cases of inflammatory peribronchial infiltration, a form of chronic pneumonia, which had been attended by fever and dulness for a number of weeks. After a time the peribronchial exudate contracted and caused bronchial dilatation, and this in later life was mistaken for signs of incipient tuberculosis—dulness, retraction of the upper lobes, prolonged expiration, bronchophony.

Resects a Rib.—DR. B. SCHARLAU said he must differ from Dr. Caillé and Dr. Winters, who advocated incision in preference to rib resection in the treatment of empyema. In former years Dr. Scharlau had employed the various methods in vogue, including incision, but in the last five years had adopted rib resection exclusively, and therefore must have good reason for doing so. During the last-named period he had resorted to resection in more than two hundred cases. He believed that in empyema, as in all cases of large abscess, there should be a free opening for drainage. In about fifty per cent. of cases in children there were large clots in addition to purulent fluid, which must remain unless a free opening were made and they could be reached if necessary by forceps. After resection he had seen recovery in ten or eleven days, often before three weeks, while after simple incision six weeks elapsed. In incision there was more danger of inaccessible hemorrhage.

Difficulties of Diagnosis.—DR. W. P. NORTHRUP thought that in a child a year or a year and a half old, to determine whether flatness on one side of the chest meant fluid or pneumonia was one of the most difficult problems. It had been something of a standing reproach between himself and his colleague at the Foundling Asylum that in a large number of cases they were unable to say positively until the aspirating needle had been used whether the physical signs meant pneumonia or fluid in the pleura. When one habitually followed up his mistakes by autopsy, in case of death, he became shaky in his confidence. The presence of a bronchial element beyond a moderate pad of fluid, he could not tell from a central pneumonia. In aspirating, internes coming there from other hospitals uniformly selected too small a needle. One could make his incision wherever he wished, provided he struck fluid. The sixth intercostal space in the axillary line in pleurisy of the right side was a fairly good place.

DR. H. D. CHAPIN was glad to hear the remarks of Dr. Northrup, for he knew of no disease in very young subjects more difficult to diagnose than empyema. The older the patient among young subjects,

the easier it became to recognize the physical signs. Many children were lost, owing to the fact that the true nature of the disease was overlooked until late. According to his experience, bulging of the chest did not occur in children with a moderate amount of fluid. The reason was that the point of least resistance in them was the lung. The physical signs of bronchial breathing were also apt to be present. For these reasons, in cases of doubt he used the needle, a large one. As Dr. Koplik had stated, a large number of cases of empyema followed pneumonia. Notwithstanding the fact that the physical signs might remain much the same, our suspicions should be aroused if the patient assumed a pinched, anxious look, and we should then use the needle.

In regard to treatment, at a discussion a year or more ago, before the County Medical Society, all surgeons favored resection of a rib, while the physicians favored incision. Wishing to form an unprejudiced opinion, he afterward resected a rib in some cases, but had again returned to incision, for the reason that in two cases sinuses had formed after resection, which were difficult to heal. It was time to resect when the patient failed to recover under treatment by incision.

THE PRESIDENT was requested to speak, and said that at the meeting referred to by Dr. Chapin the discussion turned chiefly upon technique of operation, he believed. Now, when physicians were able to report one hundred or more cases of resection of rib, he thought it about time for surgeons to go to them for information. At any rate he had found himself called upon to do the operation less frequently than formerly. He was convinced, however, that resection was preferable to incision, for the discharge was freer, the fibrous clots were more promptly expelled, and the patients recovered sooner.

DR. CRANDALL thought an important point brought out in the discussion was the fact that empyema in children was almost always secondary, and usually secondary to pneumonia. It should teach us to be careful about criticising the physician who had seen the patient before us, and who had only diagnosticated pneumonia. The chances were that he was correct, the patient having started out with simple pneumonia, empyema developing afterward.

DR. WINTERS thought simple incision alone should be practised in recent cases of empyema, resection of rib not until later, if at all, and he had found this the practice in hospitals which he had visited in England the past summer. Diagnosis ought not to be difficult. During inspiration, press backward and upward with the finger on the pit of the stomach to prevent descent of the diaphragm, and a sound would be obtained entirely different from that produced by solidified lung. A most important sign was the peculiar sense of resistance to the finger used as a pleximeter during percussion over fluid.

Committee on Library Fund.—In accord with a resolution passed February 7, 1895, the president appointed a committee of twenty-five, together with some honorary members, for the purpose of increasing the endowment of the library to \$100,000. The following gentlemen have been induced to serve: Honorary members: Daniel S. Lamont, Roswell P. Flower, A. S. Hewitt, E. A. McAlpin, D. Willis James. Physicians: Samuel Alexander, Clement Cleveland, H. Holbrook Curtis, W. H. Draper, E. H. Grandin, Everett Herrick, E. G. Janeway, A. Jacobi, A. M. Jacobus, F. P. Kinnicutt, Hermann Knapp, H. P. Loomis, P. F. Mundé, H. D. Noyes, S. S. Purple, W. M. Polk, W. R. Pryor, A. A. Smith, M. A. Starr, Andrew H. Smith, D. M. Stimson, T. Gaillard Thomas, R. F. Weir, W. Gill Wylie, J. Blake White. On motion the president and secretary of the Academy were added to the committee.

SECTION ON GENERAL SURGERY.

Stated Meeting, January 13, 1896.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Hip-joint Amputation by the Bloodless Method.—DR. JOHN A. WYETH, being ill at home, sent several cases, which were presented by Dr. J. A. Bodine. The first case was that of a young man who had had a periosteal sarcoma of the thigh, for which Dr. Wyeth performed amputation at the hip, September 8, 1895. The bloodless method was employed by using two long pins, one of which was inserted above the anterior superior spine of the ilium, the other under and close to the symphysis pubis, and around these the rubber tourniquet was applied, to shut off the circulation. The high insertion of the pins permitted disarticulation without any interference by the tourniquet. It would be remembered that by the original technique, when the pins were inserted lower, the tourniquet had to be removed as soon as the vessels were ligated. The patient had made a good recovery.

Removal of Half of the Inferior Maxilla for Osteo-Sarcoma.—Dr. Wyeth's second patient illustrated an operation which had been performed by Dr. J. Marion Sims, in 1847, and described under the title, "Osteo-Sarcoma of the Lower Jaw; Removal of the Body of the Bone without External Mutilation." The orbicularis oris was stretched and held wide open by silk sutures passed through the lips; the lower jaw was divided at the median line and disconnected from the soft parts and its articulation, and removed. The patient was a girl, aged sixteen, who had had a tumor, shown by microscopical examination to be an osteo-sarcoma. The remaining half of the inferior maxilla was fastened to the superior maxilla, in order to hold it in natural position during healing. The operation commended itself for absence of external mutilation.

The Deformity-producing Laundry Mangle.—Dr. Wyeth's third case was one of cicatricial deformity of the hand in a young woman, produced by the laundry mangle, and for which he had transplanted to the palm of the hand skin of the abdomen. The first operation was done October 25th, consisting in dissecting the cicatricial tissue of the palm of the hand and fingers, and making attachment to a flap of skin raised on the upper margin of the abdomen. The connection between the hand and abdomen was severed on the eleventh day. With future supplementary operations it was hoped to restore considerable of the usefulness of the hand.

Perforating Ulcer of Stomach; Operation; Recovery.—DR. R. F. WEIR presented the case, which was described in our report of the Practitioners' Society, January 3d.

Restoration of the Nose.—The chairman, DR. CURTIS, presented a young man who had lost by supuration all the bones of the nose, leaving the skin intact. The skin having fallen into the cavity, Dr. Curtis performed an operation for raising it by introducing an aluminium tripod, one branch of which sank into a hole drilled into the frontal bone, the other two into holes drilled into the superior maxilla. The latter supported the alæ, and sloped downward, this being one of the precautions taken to prevent the whole framework from slipping down toward the mouth, which was its constant tendency. The platinum plate from which the support was made was one-sixteenth of an inch wide for the bridge, somewhat narrower for the branches. He would prefer the bridge somewhat wider.

DR. WEIR said that four or five years ago he introduced here this method of raising the nose with a support, it having been employed previously in France by Martin. Since then he had resorted to it ten times.

In two cases there had been difficulty from ulceration of the bridge of the nose caused by the plate, and in a third the syphilitic process had interfered, for syphilis was the usual cause of these deformities of the nose. In his first cases, too, he had drilled little holes for the reception of the tripods on the bone below, but, as it was difficult to fit the pieces into these, he had in later cases simply rested them upon the bone, where they tended to form an indentation for themselves. In two cases he separated the upper lip and introduced the support, but, being a foreign body in living tissue, it set up inflammation. The bridge must be free in the nostril, so that all secretions could escape in that direction. For saddle nose celluloid was the best material, being better borne in living tissues than any other substance. It would be remembered that the introduction of celluloid testicles was one of his hobbies.

The Finger as a Nose.—DR. JOHN GIRDNER described the case of Dr. Thomas Sabine's, in which, a number of years ago, that gentleman had transplanted the middle finger of a patient to replace the nose, which had been eaten away by lupus. To Dr. Girdner, as house surgeon, fell the task of removing the finger nail and trying to destroy the matrix. He supposed he had succeeded, but it showed a tendency to grow after the transplantation had been effected, and he had to use fuming acid a number of times before it was finally destroyed. It was nearly three months before the circulation of the finger in its new situation would justify severing its connection with the hand, and then some trouble arose from necrosis of the end of the bone constituting the tip of the nose. Photographs of the case from the Academy library were shown.

DR. SAMUEL LLOYD said that other cases had been reported, in which the nail had grown on the finger-nose.

The Operative Procedures for Removal of Large Neoplasms of the Naso-Pharynx, Antrum Maxillare, and Superior and Inferior Maxillæ.—DR. WYETH'S paper on this subject was read by Dr. Bodine. In it he described the methods of operation which he had practised in several cases of the kind indicated in the title. In 1888 a lad, aged sixteen, presented himself with a vascular fibroma growing from the vault of the naso-pharynx. Dr. Wyeth tied both external carotids, which controlled hemorrhage, and two weeks later removed the tumor through a space of three-fourths of an inch in the roof of the mouth. There was not much hemorrhage, oozing being controlled by packing. He did not deem it wise to close the surgical wound in the vault of the mouth at that time, and, as it was not done subsequently, the boy was left with a surgical cleft palate. He had then decided never to operate in this manner again. There had been no recurrence of the growth.

In 1894 a young man came under his treatment, who previously had been under the care of Dr. Rufus P. Lincoln for a number of months for treatment by galvano-cautery of a naso-pharyngeal growth. When seen by Dr. Wyeth, the tumor had attained such size as to fill the antrum of Highmore and the pterygoid fossæ, and to swell out the face and partly to displace the eye. December 12, 1894, in the presence of Dr. Lincoln and others, Dr. Wyeth operated by what he believed was a novel method, and one which he would recommend in similar cases. The patient was in very low condition, not at all suitable for a formidable operation, and he therefore introduced a syringe into a vein, to be ready to make injection of salt solution as the operation proceeded. Opium narcosis was largely relied upon, only about two drachms of chloroform being used during the hour and forty minutes.

The incision was begun on the temporal arch, about two inches back of the outer angle of the orbit, was carried along the temporal arch to near the orbital cav-

ity, was then carried parallel with and one-eighth of an inch from the edge of the orbit to near the orbital foramen, then down to the level of the ala of the nose, and then brought out near the line of opening of Steno's duct. Hemorrhage was stopped by ligation of larger vessels and by pressure. The soft tissues were not dissected up from the bone, except at the orbit for introduction of the saw and division of the junction of the malar with the frontal bone. The saw was then turned and carried downward alongside the floor of the orbital cavity, following the incision through the soft parts and cutting into the antrum of Highmore, completely exposing this and the fossæ filled by the new growth. The flap being turned back, he thoroughly removed the tumor. The bone with its skin attachments was then replaced, and the soft parts sutured. No sutures were introduced into the divided bones. The cavities had been filled with iodoform gauze which projected from the anterior inferior angle of the wound. The patient made an uninterrupted recovery; there had been no recurrence, there was no deformity of the orbit, the scar on the face was insignificant, and the orbicularis palpebrarum had not been paralyzed as one might have feared. During the operation the pulse became almost imperceptible, and the patient's condition was very serious. Saline solution was immediately injected freely, so freely that the hemorrhage during the remainder of the operation was almost that of brine.

Dr. Wyeth emphasized the value of morphine narcosis in these cases, and of the use of saline solution.

In another case, operated upon in 1895, he removed a myxomatous tumor of the naso-pharynx and antrum of Highmore of the left side, by chiselling away the anterior wall of the antrum of Highmore, after dissecting up the soft parts through a curved incision, commencing near the outer angle of the orbit and carried inward, downward, and outward, terminating near the opening of Steno's duct. For almost all neoplasms this was the best method.

Another case was one of fibro-sarcoma, which he curetted through an opening in the antrum of Highmore, but it continued to grow, and, wishing to save the patient the disfigurement which would arise from a formidable operation, he tried the toxins of erysipelas and the bacillus prodigiosus without success. Finally he succeeded in inducing an attack of erysipelas, but it had no effect on the tumor. He then removed that half of the upper jaw, leaving a rim of the orbit, which prevented deformity of that cavity. The operation was done in 1895. There had not yet been recurrence.

The two cases already presented, in which he performed the operations practised by Dr. J. Marion Sims about 1847, were then described.

Galvano-Cautery almost Uniformly Successful.

—DR. RUFUS P. LINCOLN said it was fortunate that such complications as were present in the first case related were not common. He said fortunate, for any one who witnessed the operation must be fully aware of its hazard, while admiring the skill of the operator. Dr. Lincoln had read a paper before the American Laryngological Association, in 1883, in which a table of cases of naso-pharyngeal growths operated upon by surgeons was given, and out of a total of 20 so treated, there had been 8 deaths during or attributable to the operation, and 14 recurrences within a year. To Dr. Lincoln the case related by Dr. Wyeth was of special interest, for the reason that he had operated upon the young man by a method—galvano-cautery—which had proved almost uniformly successful, but which the results showed was not sufficient to meet the requirements in this case. Recognizing this fact, he had advised the patient to submit to Dr. Wyeth's suggestion. A pertinent inquiry was, Why was not the operation, which proved successful in Dr. Wyeth's hands, resorted

to before? Dr. Lincoln answered by referring to the statistics in the paper already alluded to, and to his own experience with the galvano-cautery and *écraseur* in 14 cases, all successful but 2, one of which Dr. Wyeth had just reported, the other with cerebral symptoms and inoperable at the time when he first saw the patient. One of his cases had been operated upon nineteen years ago, and there had been no recurrence. Where extreme surgical interference was called for, he commended the method devised by Dr. Wyeth.

THE CHAIRMAN thought the operation for removal of the lower jaw better suited to cases of necrosis than those of malignant disease.

DR. HOWARD LILIENFELD expressed surprise at the use of the term "stretching the mouth." He thought it must at least involve rupturing the mucous membrane and skin. It was not like stretching the sphincter ani. The mouth had been held open by ligatures, which gave more room. In operations upon patients in very low condition, it had been suggested that, in addition to saline infusion, a rubber ligature be previously thrown around the thighs, which, in case of emergency, could be loosened, allowing more blood to enter the exsanguinated vessels.

Officers.—Dr. B. Farquhar Curtis was re-elected *Chairman*. Dr. John B. Walker was elected *Secretary*, Dr. Whitman declining a renomination.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 18, 1896:

	Cases.	Deaths.
Tuberculosis.....	128	119
Typhoid fever.....	3	5
Scarlet fever.....	214	21
Cerebro-spinal meningitis.....	1	3
Measles.....	330	22
Diphtheria.....	332	40
Small-pox.....	1	0

Extra Dispensary Facilities.—*Dispensary Patient to Medical Attendant.*—Can I hang my sealskin where it would be safe until you get done with me?

"Certainly, madam; kindly wait your turn and get a check from the superintendent."

"How long must my coachman wait?"

"He must stand in line until his number is called."

Foreign Medical Practitioners in Paris.—It is said that there are in Paris as many as 521 foreign medical men, or rather more than one-sixth of the total number (2,922) of Paris physicians.

Dirty Thermometers.—Those who are constantly preaching the germ causes of disease are the very fellows who many times are as careless as their unbelieving friends. How frequently do we see physicians take the temperature of their patients, regardless of the existing disease, wipe the instrument with their handkerchief, which is the linen most liable to be full of germs, or a towel, or even use the sheet, and carefully place it away in a case prepared with a small amount of absorbent cotton in the bottom to keep from breaking, and unintentionally preserving the germs from time to time, to be conveyed to the next unfortunate, who may be the first patient called upon. This seems to be a very simple thing to discuss, but any reasonable person can readily see the necessity of having his thermometer thoroughly cleaned every time it is used. It should be washed

with soap and water, and if any cotton is used in the bottom of your case, let it be sublimated cotton, and occasionally renew it.—*Charlotte Medical Journal*.

An American Medical Poet.—Among the American medical poets about whom little is known, is Thomas Holley Chivers. He was a Georgia doctor, and the author of seven or eight volumes of verse, issued between 1834 and 1858. Mr. Joel Benton has recently called attention to him in *Collier's Weekly* as being the predecessor of Poe. It is not only the swing of his verse, says Mr. Benton, but the epithets of this bizarre poet that show the mannerisms of Poe. Any one who has ever read Poe, and would then read the following verse from the poem called "Lily Adair," will see at once that though Poe was a better poet, he followed the style of the Georgia doctor:

Her eyes, lily lidded, were azure,
Cerulean, celestial, divine—
Suffused with the soul light of pleasure,
Which drew all the soul out of mine.
She had all the rich grace of the Graces,
And all that they had not to spare;
For it took all their beautiful faces
To make one for Lily Adair—
For my Christ-like Lily Adair,
For my Heaven-born Lily Adair,
For my beautiful, dutiful Lily Adair.

Aseptic Communion Cups in California.—According to the *Sun*, the question of contagion from the use of a common communion cup in the service of the sacrament in Protestant churches is to be brought before the State Board of Health of California. The Rev. V. Marshall Law, an Episcopal rector of Oakland, invented and patented a hygienic communion cup, but was snubbed by his superiors in the church when he asked them to adopt it. Dr. Law believes in his cup, and in the danger of the common cup, and proposes to ask the local and the State Boards of Health to pass on the question of communion cups in general and the miscellaneous way in which they are used. He claims that the ritual of the church is subject to the laws of the commonwealth, and will ask the authorities to take some action in the interest of the public health.

Crossed Otorrhagia.—M. Le Fort has pointed out a new sign in severe fractures of the base of the skull, which is very important from the point of view of prognosis. He gives the histories of three cases of fracture of the skull, with autopsies. All three fractures presented a similar peculiarity, viz., that the fracture of the vault of the cranium had produced a complete fracture of the petrous portion of the temporal bone on the opposite side. In the first case the fracture of the vault was in the temporal region; in the second, in the fronto-temporal region; and in the third, in the occipital region. In all three cases there was bleeding from the ear on the side opposite to that which was struck. Incomplete fractures of the petrous portion of the temporal bone following a fracture of the vault are common enough, but not complete fractures. Of course, in making use of this sign, care must be taken that the hemorrhage is not due to some trivial external cause.—*Medical Times*.

The Narrow Pelvis of the South German Woman.—Dr. Schnltz, of Rostock, says that narrow pelvis is comparatively rare among North German women. Among 2,083 pelvises examined at the clinic of Rostock only 65, or 3.2 per cent., were universally contracted pelvises; 93, or 4.5 per cent., were non-rachitic flat pelvises, and only 1 per cent. rachitic pelvises. In the Berne clinic, on the other hand, narrow pelvis existed in 22 per cent. of the cases, and in the Dresden clinic in 24 per cent. As a consequence, absolute and relative Cæsarean section, symphysiotomy, and

induction of premature labor were very rare; prophylactic turning was the usual operation.

Diphtheria Antitoxin in Montreal.—The report of the Protestant section of the Contagious Diseases Hospital for the last six months gives the result of the antitoxin treatment as follows: Out of 34 cases of diphtheria treated with antitoxin there were 4 deaths, while out of 12 which did not receive the treatment 2 deaths occurred.

The Matteawan Hospital for Criminal Insane, New York.—The Hannigan trial and similar proceedings, where the plea of insanity prevails as a defence for crime, naturally suggests to many an inquiry as to what provision the State of New York has made for the custody of the criminal insane. One of the most recently erected institutions in the State is the Matteawan State Hospital, yet next to Utica it is the oldest State asylum for the insane, having been opened at Auburn for the reception of patients in February, 1859, nearly thirty-seven years ago, antedating in this respect the English asylum for criminal lunatics at Broadmoor. Originally established for the treatment of insane convicts, its scope from time to time has been widened until at present it practically receives all the criminal insane in the State, both from the courts and from penal institutions. It is discretionary with the judges making commitments to send patients to any of the State hospitals, but with very few exceptions all cases of insanity charged with crime are committed directly to Matteawan, or subsequently reach there by transfer. The criminal insane as a class have always been objectionable as patients in the civil hospitals, partly from the nature of their crimes and partly from the greater restrictions necessary for their safe custody, which more or less curtails the general privileges of the house, and also because of the fact that over seventy-five per cent. of them possess homicidal and dangerous tendencies. The power of transferring such patients from the other State hospitals to Matteawan, which was formerly wholly vested in the Supreme Court, is now exercised as well by the State Commission in Lunacy. In the thirty-seven years of its existence the hospital has treated over one thousand seven hundred patients. During the past four years the increase in population has been very rapid, and at present the number of inmates is five hundred and thirty-four, nearly its full capacity. Only about one-third of the inmates are patients who are undergoing sentence, and these upon recovery are returned to penal custody. It frequently happens that many of the admissions from penal institutions are of patients who evidently were insane at the time of their trial and yet in whose cases either the disease was not recognized or the plea of insanity failed to be established. In this connection it is interesting to observe that seventeen per cent. of the life men in the State are inmates of the Matteawan State Hospital. Their insanity in some instances was the causative factor of the crime. In others the disease developed subsequent to conviction. Among court cases, crimes against the person are by far the most prevalent and delusions of persecution almost universal. The rate of recovery among this class is not large, and many patients the details of whose homicidal acts filled the public press some years ago are still inmates there or have gone to swell the list of the great majority. The accumulation of such a class at this hospital relieves the other hospitals of a class undesirable and objectionable, and allows them a freedom in this respect which they have long sought to procure.

A special committee of the English House of Lords in 1860 reported that it was inexpedient to confine, among the ordinary insane, lunatics charged with

crime. The asylum at Broadmoor and that at Matteawan are conducted along similar lines. At the former institution dangerous patients are detained during "the Queen's pleasure," and at the latter until discharged by due process of law. By reason of the present large population at Matteawan, it is necessary that increased provisions be made for the custody of the criminal insane, and in so doing an effort will be made to furnish accommodations whereby the convicted patients undergoing sentence shall be cared for separately from those who are "criminals" simply because of their insanity, which for many obvious reasons is desirable. While such patients themselves have always been and still are objectionable in the general hospitals for the insane, yet in turn they should be kept from contact with the habitual criminal, whose insanity usually arises after conviction as a passing incident in a life devoted to criminal acts, and does not enter as a factor into the determination of this responsibility. It is only a step in the direction so frequently pointed by medical men that measures taken by the law for the repression of crime should be suited to individuals and not solely to crimes.

The Matteawan State Hospital is situated a few miles from New York, in the midst of the most charming scenery of the Hudson River, and commands the widest view of the upper Highlands and of the Hudson River Valley above Fishkill.

The Egyptian Origin of many Modern Jokes is well known. The Egyptian origin of many medical recipes has recently been demonstrated by Prof. Georg Ebers. Old medical recipe books, both English and German, contained, down to the very end of last century, the formulæ, if they may be so termed, of remedies which are found in ancient Egyptian papyri. The problem is, how did these prescriptions find their way from Egypt to Europe? Clearly not through the Greek writers, since their works contain nothing of the kind. Ebers suggests that they were handed down by the famous old school of Salerno. The teachers in that school are known to have been acquainted with Egyptian medicines through Coptic and Arabic translations. One of the most celebrated of them, Constantinus Africanus, had visited Egypt, and he "conveyed" a good deal of the medical lore which he learned there into his own writings. Ebers gives a number of examples, showing how recipes for eye lotions, methods of treating prolapse of the womb, predicting the sex of an unborn child, etc., which appeared in old English and German books, could be traced back to Egyptian sources.

Mediæval Gynecology.—Dr. W. G. S. Robertson gives (*Edinburgh Medical and Surgical Journal*) the following description taken from the works of Father Mayster Alexis of Piemont, who lived in the latter part of the sixteenth century: The tampon and postural method were evidently well known at that time: "To heale a woman that hath the matrice out of her natural place. Take a flint stone that hath been alwaies in the earth and not taken the aire, and put it in some basket covered in a great fire, and when it is verie hotte put it in a little tubbe or barrell, and wet it with vinegar cast upon it, and cause the woman to stand over it to receive the smoake or parfume of it, and then let her goe to bed. Ye shall after this take the juice of Rue and make a little rounde ball of cotton, whereunto ye shall tie a threede, and then dippe the saied ball in the saied juice of Rue, and put it into the mouth of the matrice, the whiche will incontinent take the ball and drawe it in, and then it will return into his natural place again. But you must binde and tie the ball sure and well, least peradventure it should remaine within. After this an ointment

is to be applied to the reynes of her backe, and laye hotte towe upon it, and then swaddle her as women do young infantes. And so she must be laied in her bed with her bellie upwarde and her heade lower than her buttockes. This must ye doe from night to night three times and she shall be healed. She must also eate hot things in operation, as pigeons and hennes, with spices and other like things."

House Nerves.—This is the latest name invented by medical experts for the peculiarly depressing set of ailments which afflict people who stay indoors too much. The discovery of the novel malady is due to a journal devoted to science, and it is a mark of unusual and undoubted condescension that the name of the disease should be so simple and so easily understood. There was nothing, as far as can be seen, to prevent the scientific godfathers from naming their child "ækoganglia," or something equally terrifying to the unsophisticated. Merely as "house nerves" we can regard the ailment with some complacency; but for all that it is not a thing to be laughed at. All over Europe the rush of existence is playing havoc with our sensitive cerebro-spinal fibres. We recognize all the symptoms which the inventors of "house nerves" describe as quite common in England to-day. They are "low spirits and brooding," much irritability, and a generally "morbid habit" of mind. "Women," we read, especially women who are delicate and afraid to go out owing to the weather, are those who suffer most from this malady. They have a way of imagining that something awful is happening to their husbands or children when they are out of sight; they "conjure up accidents, analyze their feelings, and lose their power of will." All this occurs because people are too sedentary, and stay at home too constantly. Unfortunately, a housewife, as her name implies, is one whose duty is to stay at home for a considerable portion of each day; and all the mischief arises from her not being able to tear herself away from home ties and forget all about them in some form of out-of-door amusement or occupation. A woman who gets "house nerves" begins to study herself, her own wants and ailments and loneliness, to a painful extent, until—we are solemnly warned—she "is on a fair road to an asylum, did she but know it." Journals devoted to medical science often indulge in these pleasant little predictions; yet the reading public never accuse their editors of suffering from "science nerves." Putting aside the hint of the asylum, as both alarmist and irrelevant, we have to admit that there is a great deal of truth in the idea that "all home and no spree makes Jill a dull she." Not only does it make her dull, but it often, in the humbler walks of life at any rate, gives rise to that "nagging," which drives husband to the public house or deplorable personal violence. There may be happy lands—say Bœotia or the "peasant-state" of Bulgaria—where nerves are unknown. Probably they affect the south of Europe less than the north, because there the climate allows of life being passed more in the open air, and sunshine and ozone are great nerve tonics. In Russia the consumption of tea and Tolstoi leads inevitably to neurotic catastrophe. Nor is Europe the only sufferer. In no country in the world are human nerves exposed to greater wear and tear than in the United States. The combined effects of the negro question, unlimited candy, an addiction to rapid eating, iced drinks, and business hurry, are too powerful for any nerves not built of cast-iron to withstand; and thus it comes about the typical American is a neurotic patient long before he has attained to middle age. Fortunately, the disease is not left without a remedy, and the prescription for a person afflicted with "house nerves" is a very agreeable one. There

is no help to be got from medicine or doctors. All that has to be done is to pay visits to others, to take walks in the open air and sunshine, and to go in generally for gayety and innocent amusements. The patient is also recommended to "repress every morbid thought, as it arises, or expel it by thinking of a necessary duty." This advice is, perhaps, more easily given than followed. Hundreds of people would be only too delighted to repress morbid thoughts, but the more they try to repress them the more morbid do they become. It is sad to think that not only adults, but also "imaginative children," suffer from the "domestic nerve," and when such is the case they should be sent to "play with merry companions," whose merriment, let us hope, will be subdued enough to spare the "house nerves" of other people. Of course, there is nothing strikingly novel about the advice to try out-of-door exercise for morbid mental conditions; but these "hints to those about to go into hysterics," will be of use if they help to impress on us the fact that a good deal of the excitability, the irritability, and the depression which afflict so many nowadays are really of a nature of a disease and should be treated with common-sense remedies, instead of useless reproaches.—*Calcutta Medical Review.*

Suicide in European Cities.—Recent vital statistics show the following numbers of cases of suicide per 10,000 of population: Munich, 1.93; Berlin, 2.98; Vienna, 3.2; Brussels, 3.29; Paris, 3.6; Breslau, 3.91. The Vienna correspondent of *The Lancet* furnishes some interesting data concerning suicides in that city. In every 100 cases, 77 were men and 23 women. Adolescents appear to have even more frequent recourse to this method of terminating their real or supposed miseries, the highest rate being registered at the age of sixteen to twenty-five years. Among 100 suicides, 32.5 ended their days by hanging; 28.5 by pistol-shots; 22.4 by poisoning; 5.8 by drowning. With respect to the poisons, cyanide of potassium was resorted to in 12.7 of the cases, caustic lye in 22.7, phosphorus in 26.1, and sulphuric acid in 7.2. As for seasonable distribution the proportions were: in January, 8.5 per cent.; in February, 7.6 per cent.; in March, 8.9 per cent.; in April, 9.1 per cent.; in May, 10.5 per cent.; in June, 8.7 per cent.; in July, 8.1 per cent.; in August, 7.2 per cent.; in September, 7.4 per cent.; in October, 8.3 per cent.; in November, 7.8 per cent., and in December, 7.9 per cent.

Contraindicated during Pregnancy.—Dr. Huguenin mentions as chief of the remedies which are dangerous to the pregnant woman salicylate of sodium and ergot. Purgatives—castor oil, mineral salts, and especially aloes—should be avoided. Oxalic acid and its salts—oxalate of potash, etc.—may prove dangerous. Antipyrin frequently taken inhibits the lacteal secretion; cocaine locally applied for fissured nipples has the same effect, and should be proscribed for nursing women. As to operative measures, they are not absolutely contraindicated; we may, for example, extirpate a peri-uterine tumor, the development of which hinders pregnancy, provided the operation is speedy and little blood lost. It is better to wait until the fourth or fifth month before operating. Operations in the vagina or uterus, no matter how minor, should be avoided in order to avoid suspicions of abortion in the patient's mind.—*Journal of the American Medical Association.*

Alimentary Glycosuria.—The temporary presence of sugar in the urine can be readily induced by the ingestion of one hundred grains of sugar in hysterical subjects, pregnant women, those poisoned by phosphorus, and in cases of atrophic cirrhosis.—JAKSCH, *Prag. Med. Woch.*, No. 27, 1895.

A CONTRIBUTION TO BRAIN SURGERY, WITH SPECIAL REFERENCE TO BRAIN TUMORS.¹

By M. ALLEN STARR, M.D., Ph.D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF
PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA
COLLEGE, NEW YORK; CONSULTING NEUROLOGIST TO THE PRESBYTERIAN
AND ORTHOPÆDIC HOSPITALS, AND TO THE NEW YORK EYE AND EAR IN-
FIRMARY.

GENTLEMEN: Before entering upon the subject of operation for brain tumors, which I have been asked to discuss, I desire to say a few words regarding operative interference in cases of epilepsy. It is, of course, admitted by all that in ordinary idiopathic epilepsy with general convulsions, or with attacks of a *petit mal* type, there is no reason for any surgical interference. The only type of epilepsy in which a question of operation can arise is that of so-called cortical epilepsy, where an irritant lesion of one region of the brain produces localized spasms. Such lesions may be traumatic in origin, from fractures, localized meningitis, small hemorrhages, or cysts; or the epilepsy may be the first sign of a beginning tumor, abscess, or sclerotic patch. It is for this class of cases that operations have been very largely undertaken in the past and are still being done.

In my book on "Brain Surgery," published in March, 1893, I collected twenty-nine cases from literature and recorded thirteen cases of my own, in which operations had been done for the relief of this condition. Thirteen of these were reported as cured. Since that time a very large number of cases have been reported, and I have had eight more cases operated upon. I will not take your time by any detailed statement of these cases, but wish to say that I am exceedingly disappointed with the final result of operations in this type of disease. Experience seems to show that, although after an operation a cessation of attacks may occur, these attacks are almost certain in the end to recur, and hence that the patients are not actually cured. Therefore I am becoming more and more reluctant, even in cases of well-defined cortical epilepsy, whether of traumatic or of spontaneous origin, to recommend surgical interference.

In cases in which the brain itself has been injured and a cicatrix has formed there exists a focus of irritation, and it is not possible by excision of this cicatrix to produce a result very different from that which is already present, for the cicatrix of the incision made by the surgeon is little different from that produced by a trauma, and hence in these cases I regret to say that a little permanent effect is produced.

Turning now to the subject of brain tumors, it must be stated at the onset that the experience of investigators during the past three years has seemed to confirm the statement which I made in "Brain Surgery," that only about seven per cent. of tumors of the brain are open to operation. The difficulties in the way of operation in brain tumors are, first, the diffi-

culty of locating the tumor accurately from the symptoms alone, and, second, the difficulty of reaching the tumor when accurate localization is possible.

There are a number of distinguished surgeons who have advocated a removal of a portion of the skull in every case where the diagnosis of brain tumor is made, irrespective of the possibility of locating the tumor, and irrespective of the possibility of excising it. The object of such an operation is to relieve the intracranial pressure produced by the growth of the tumor and thus to relieve the symptoms of headache, vertigo, vomiting, and optic neuritis. The experience of many surgeons who have trephined for a brain tumor without finding it, but who have seen a certain amount of relief to these symptoms after an operation has led to this suggestion. Thus Park¹ and Horsley² have recorded cases in which considerable relief was obtained. Clarke and Norton³ operated for the relief of pressure by taking out a section of bone from the parietal region. The headache and the optic neuritis subsided after the operation, but inasmuch as the tumor was not removed the symptoms gradually returned, and the relief lasted only about five months. Diller,⁴ operating under the same circumstances, was not equally successful in relieving his patient, for the symptoms continued about the same after the operation, and the patient died a month later. Albert⁵ reports three cases operated upon in this manner. In one there was no improvement whatever, in the other two a slight improvement, lasting through a month or six weeks, was obtained.

Horsley has urged this procedure very strongly and has even gone so far as to state that it may have a beneficial effect upon the growth of a tumor. He has recorded two cases in which relief of intracranial pressure has been followed, not only by a subsidence of the symptoms, but apparently by a progressive decrease and final absorption of the tumor; the patients recovering after a year from all cerebral symptoms.

I have recommended this procedure in one case at the Presbyterian Hospital in a patient seen with Dr. A. H. Smith, and subsequently operated upon by Dr. McCosh. The man had all the symptoms of a tumor of the corpora quadrigemina, with very great distention of the ventricles, producing a tremendous increase of intracranial pressure. The removal of a considerable section of the skull from the parietal region relieved his headache for a few weeks, but had no effect upon the optic neuritis or upon the other symptoms, and he subsequently died.

These facts should certainly be considered in the management of any case of brain tumor. And while at first sight it may appear that the operation of trephining in such cases merely prolongs the life of a patient whose sufferings are extreme and whose death is sure to follow, and is in no sense curative, yet it is well known that surgeons undertake operations for the removal of tumors in other parts of the body, even when it seems probable that these tumors will recur;

and there are many patients who prefer to take the risks of an operation in order to secure a longer lease of life. It is also to be remembered that a marked change in the circulatory conditions, consequent upon the relief of the intracranial pressure, may in some cases aid in the effect of the absorptive power of some drugs. For it is not to be forgotten that there are cases of brain tumor in which the diagnosis is perfectly certain, which have recovered under the use of mercurial inunctions together with very large doses of iodide of potassium. Oppenheim,¹ in his recent monograph on brain tumors, calls particular attention to this fact, and I desire to put on record a case which offers a striking confirmation of it. I do not allude in this connection to cases of gummy tumor, for I think it is generally admitted that under the American system of treatment by inunctions of mercury, continued to the point of salivation, and very large doses, as high as five hundred grains a day of iodide of potassium, gummy tumors can be absorbed. I have, personally, records of four such tumors absolutely cured and now under observation a year or more since the cure, and I have no doubt that my experience in this respect can be duplicated by many who are present.

The following case, however, is one in which syphilis could be absolutely excluded. The patient was a boy, sixteen years of age, of perfectly healthy parents, there being no direct or indirect history of syphilis in either parent, and the boy himself presenting no evidence, direct or indirect, of having had the disease. In March, 1895, he began to suffer from a disturbance of his eyesight, and it was noticed that his eyes had a peculiar appearance. He was taken to a certain specialist in New York, who immediately discovered muscular insufficiency and divided the internal recti without any relief. Two weeks later he began to suffer from very intense headaches, vomiting, and marked mental dulness, and it was noticed on every occasion that he staggered slightly in walking. Lateral oscillation of the eyeballs was then noticed, and his headaches, which increased in intensity, interfered with his sleep at night. On April 24th, when I first saw him in consultation with Dr. Story, of Flushing, L. I., the boy was very ill. He was confined to bed and any motion increased the intense headache from which he constantly suffered. He was extremely emaciated, and frequent vomiting was attended by great vertigo and prostration. His eyes were prominent, his pupils were dilated, there was a slight deviation of the left eye outward, he saw double, vision was reduced two-thirds, and there was very marked nystagmus on any lateral movement of the eyes. Examination by the ophthalmoscope revealed a double optic neuritis, with great distention of the veins but without hemorrhages in the retina. There was no paralysis of the face, but he complained of numbness in the left side of the face and some weakness in the muscles of mastication on the left side of the jaw. His tongue deviated to the left. There were no paralysis or ataxia of the hands and no disturbances of sensation in the extremities or body. There was no paralysis or ataxia of the legs when at rest, and his knee jerks were normal. There was no clonus. On standing up, his head fell forward, but he was able to straighten it with some effort, holding it, however, somewhat forward and toward the left. He staggered painfully in standing and in walking, so that he was unable to walk without assistance. The staggering was of the type recognized as cerebellar. There was considerable ringing in the left ear, but his hearing was the same on both sides. He had had on three occasions retention of urine which had to be relieved by a catheter, and he was extremely constipated.

With these general symptoms of brain tumor, and

with the local symptoms of cerebellar disease, together with an affection of the fifth, eighth, and twelfth nerves on the left side, it seemed evident that this boy must have a tumor involving the cerebellum and producing compression of the left side of the cerebral axis; a tumor, in a word, whose position was such as to make any operation absolutely impossible. In the absence of any history of syphilis it seemed proper to give an absolutely unfavorable prognosis, and yet to resort to inunctions and large doses of iodide as affording the only possible hope. These were immediately begun and the iodide rapidly run up to two hundred and fifty grains a day. A steady improvement began in about two weeks after the treatment was instituted, and by June 15th he was up and about, without headaches, without vomiting, and walking without assistance quite well. He still staggered slightly, however, with a tendency to go toward the left; his tongue still deviated to the left. The left side of his face was still hyperæsthetic and at times painful. His eyesight was improved and the optic neuritis was subsiding. The improvement went on during the entire summer, and at present the boy is quite well, with the exception of nystagmus and a slight right facial paralysis which has developed slowly. The appearance of his eyes is such as to suggest the previous existence of a neuritis, though his sight is normal. He is still taking two drachms of the iodide of potassium daily.

This case then shows that even in some individuals where there is no history of syphilis medical treatment for a brain tumor occasionally succeeds. Whether this treatment may be aided by diminution of the intracranial pressure may be left an open question.

In three cases of cysto-sarcoma in which the diagnosis was confirmed either by operation or autopsy, I have seen very great improvement in the symptoms follow a course of treatment with mercurial inunctions and iodide of potassium. The only manner in which such relief of symptoms could have occurred must have been by an absorption of the fluid in the cystic spaces of the tumor. In another case of cerebellar tumor this treatment was, however, without effect.

It must, therefore, be admitted that anything which diminishes the intracranial tension in cases of tumor may relieve the symptoms for a time, hence trephining for the relief of pressure is justifiable.

Turning now, however, from symptomatic treatment to the radical cure of brain tumors by removal, it is to be remembered that the necessary preliminaries to any operation for brain tumor must be accurate diagnosis of its position and a reasonable possibility of reaching it.

First, in regard to the diagnosis, it is now possible to distinguish sharply between the general symptoms common to tumors in any location—such as headache, optic neuritis with consequent blindness, vomiting, vertigo, mental dulness, polyuria, and general exhaustion—and those that are strictly local in their significance, such as spasms, paralysis, the various forms of aphasia, hemianopsia, anæsthesia, cerebellar staggering, rotary movements, and cranial nerve palsies. There is one local symptom not generally known to which I desire to call your attention. It was first pointed out by Macewen. It is a change in the percussion note elicited by auscultatory percussion of the skull. I can confirm Macewen's statement that on the side of the tumor or abscess there is sometimes found a clearer, higher-pitched, and more resonant note than upon the opposite side. This is not uniformly obtained. Horsley has recently noticed that tenderness to pressure is often found over a tumor when tenderness to percussion cannot be elicited. It is upon the local symptoms that the decision with regard to the possibility of operation distinctly rests. In a small

¹ "Die Geschwülste des Gehirns," Wien, 1896.

proportion of brain tumors it seems easy to determine the fact that the tumor must lie in a definite position, and if that position is one upon the convexity of the hemisphere where access to it through the skull is easy, it seems justifiable to undertake an operation. Yet my own experience and that of other operators has convinced me that even in regard to these local symptoms mistakes are possible.

Thus in a patient operated upon by Dr. McBurney for me in November, 1895, a patient who had been carefully watched since May and had presented symptoms of a tumor located in the arm centre of the left hemisphere (viz., all the general symptoms of brain tumor, and spasms beginning in and for a time limited to the hand and face, followed by temporary paresis), a large exposure of the cortex failed to reveal the existence of a tumor on or near it, and the subsequent autopsy showed that the tumor (a sarcoma) had lain deep within the centrum ovale and had invaded the basal ganglia, although the symptoms pointed distinctly to the cortex as its point of origin. I think it is still impossible to distinguish accurately between cortical and subcortical tumors, and that no practical advance has been made in the differential diagnosis since the classical article of Seguin and Weir published in 1888.¹

Another difficulty in the way of operation is the fact that the nature of the tumor is always a matter of uncertainty until the tumor is exposed. Thus in a case operated upon by Dr. McBurney for me in May, 1895, where every symptom pointed to a tumor of small extent in the leg centre of the right hemisphere, it was found at the operation that a very extensive glioma occupied both central convolutions and extended downward as low as the face centres, so vascular in its character as to make its incision or excision impossible, and so imperfectly defined in its extent as to make it impossible to accurately determine its limits. I am willing to admit that in a case such as this very extensive excision of the brain is possible. Thus in September last, in London, I saw Mr. Horsley cut out a portion of brain substance, measuring four inches by three inches in surface extent and one and a half inches in thickness, from the motor area of the brain for the relief of chronic congenital athetosis with paralysis, and by careful tying of the vessels before the brain itself was incised, the method employed being that of passing horsehair sutures with an aneurism needle deep into the brain and out again all the way around the contemplated incision, he caused little hemorrhage and the life of the patient did not seem to be endangered by the extensive loss of brain substance. It is also well known from the experience of treatment in brain abscess that a large amount of cerebral tissue may be lost without fatal result, and the experience of Von Bramann and of Czerny has confirmed the possibility of large excisions of glioma of the brain without loss of life. Yet here again the fact confronts us, that although the patient may recover from the operation, he does not recover from his disease, for symptoms of a permanent character remain, which insure a life of invalidism.

It is only when the tumor is small, lies on but does not invade the cortex, and can be removed without serious damage that the prognosis is absolutely good. This was the condition in an angioma removed by Dr. McCosh at the Presbyterian Hospital in November, 1894. The patient had developed epilepsy with maniacal attacks after a blow on the left parietal region which had left a very tender and painful spot on the skull. There were few symptoms of tumor, but trephining at this spot revealed the existence of a small angioma, easily removable. The boy recovered and has been entirely well ever since.

¹ Amer. Jour. Med. Sci., July-Sept., 1888.

Secondly, coming now to the record of what has been done in the treatment of brain tumors by operation, I have summed up the results in the following table. This table is made from the list of brain tumors to be found in my "Brain Surgery" up to 1893 (ninety-seven in number) and from the lists of tumors here appended (sixty-five in number) which I have gathered from medical literature between 1893 and January 1, 1896.

Table of Results of Operations for Brain Tumor.

	Cere-bral.	Cere-bellar.	Total.
Total number of cases operated upon for brain tumor.....	137	25	162
Cases in which tumor was not found.....	39	9	48
Cases in which tumor was found but not removed.....	5	2	7
Cases in which tumor was removed and patient recovered.....	65	7	72
Cases in which tumor was removed and patient died.....	28	7	35

It will be seen that these cases fall into three categories:

1. Cases in which the tumor was not found at the operation. These cases number forty-eight, of which thirteen only have been recorded within the past three years. The errors in diagnosis which have led to a futile operation have been in the majority of these cases inevitable. In many of the cases the symptoms have pointed to the motor area or to the cerebellum as the site of the tumor. The tumor has really lain either deep beneath the cortex, or at some distance from the motor region, or in the frontal lobes. Since tumors at some distance from the motor region may cause motor symptoms indirectly by irritation or by pressure, it seems impossible in some cases to avoid this first error. The occurrence of ataxia of a cerebellar type from lesions of the frontal lobes has led to the second error. Bruns¹ was the first to point out the fact that frontal lesions often cause ataxia of a cerebellar type, and this fact has been confirmed by Cenas,² Dinkler³ and Hermanidas.⁴ In a recent monograph on brain tumors, Bruns⁵ has pointed out the differential points between frontal and cerebellar ataxia, as follows: frontal ataxia is often associated with hemiparesis or with monoparesis; there is usually a localized tenderness to percussion or to pressure over the frontal region; optic neuritis occurs late in the course of the disease, and mental dulness is an early symptom. In cerebellar ataxia there is rarely hemiplegia; there is no tenderness over the frontal region; optic neuritis with hemorrhage in the retina occurs very early in the course of the disease and is attended by blindness, and while other symptoms of brain tumor such as vertigo, vomiting, and slowness of pulse develop early, mental symptoms such as dulness and apathy occur late. These points should be noticed, inasmuch as a staggering gait has been supposed to be quite characteristic of cerebellar lesions. It is well known that operations for cerebellar tumors have a more unfavorable prognosis than those for tumors in any other portion of the brain. In fact out of twenty-five operations for cerebellar tumor, while seven cases have recovered from the operation and have lived a few weeks, but two have been really permanently benefited. It is possible, therefore, that operation has been refused to some cases which have been considered as cerebellar because of the gait, when as a matter of fact the tumor lay in the frontal region and was accessible. In a recent case of Stewart and Annandale⁶ of successful operation for cerebellar tumor, consider-

⁵ Gehirntumoren. "Realencyclopädie d. ges. Heilk." Encyclop. Jahrb., v. Bd., 1895.

⁶ Edinburgh Hospital Reports, 1895.

able stress was laid upon the fact that the pain suffered was in the opposite frontal region. This is another indication of the intimate relation between the cerebellum and the frontal lobes. I think it is evident, therefore, that with regard to the cases in which tumor has not been found at the operation a more careful study of the symptoms might in future prevent mistakes.

2. The second class of cases are those in which a tumor was found at the operation but its removal was impossible. This was usually due to the nature of the tumor. In any case the nature of the tumor is a matter of uncertainty. Should it turn out to be a glioma it is often very difficult of removal, yet Von Bramann has recorded¹ a case of glioma in which three operations have been performed, each a year after the preceding one, with a consequent prolongation of the patient's life, and, as already stated, it is not dangerous to make large incisions into the brain. Cases in which the removal has been impossible, however, are cases where the tumor has been very diffuse, very vascular, and very large. In all these cases it seems to me that an earlier attempt at operation might have succeeded. It is noticeable that while prior to 1893 five such cases are recorded, since 1893 but four such have been put on record, and this appears to show that with greater care in the selection of cases for operation, and an earlier adoption of this procedure, this class of cases will be eliminated in the future.

3. We come now, thirdly, to the class in which tumor was successfully diagnosticated, was found at the operation, and was removed. These now number 107, with 72 recoveries from the operation—a very satisfactory record when it is remembered that the first case in which operation was undertaken occurred in 1885. It is to be recollected that statistics show that out of one hundred and twenty autopsies in a hospital, brain tumor is found in one case only, and I have already stated that only seven per cent. of brain tumors are open to operation.² Hence this record shows that the operation is now being undertaken in almost all suitable cases, and it is also a satisfaction to find that, in the cases more recently recorded, the percentage of recoveries from the operation is greater, and the percentage of final recovery from all symptoms of disease is also greater. It has been an objection to the operation, that even when tumors are removed they are liable to recur, and that the destruction of brain tissue produced before the removal renders the patient a helpless invalid under all circumstances. This statement, however, is erroneous; for sufficient time has now passed to warrant the assertion that many patients are alive whose tumors were taken out successfully, four, five, or six years ago and many other patients are now alive, free from all symptoms, from whose brains tumors have been removed. I cannot but feel that in the future the prognosis in such operations will be more favorable than it is at present, and that we have every reason to go on with this work of removal.

As we look over the history of the successful cases it is evident that the most favorable cases for operation are those in which the tumor has been situated in the motor region of the brain, producing first localized spasms and then localized paralysis, or in the speech area of the brain, or in the visual areas of the brain. In all these areas the local diagnosis is easy, acces-

sion to the cortex is easy, and removal of the tumor should not present many difficulties in the hands of a skilful surgeon.

In the following table will be found a list of the varieties of brain tumor operated upon during the past three years and the result.

Table II. Variety of Tumor Removed and Results—1893 to 1896.—

Variety.	Recovered.	Died.
Sarcoma.....	10	5
Glioma.....	3	1
Glio-sarcoma.....	2	0
Cystic.....	3	5
Tubercular.....	3	3
Gumma.....	1	2
Fibroma.....	0	1
Angioma.....	1	0
Not stated.....	3	4
	26	21

It is evident that sarcoma is a tumor most frequently removed at the operation, and with the best prognosis. There appears to be little difficulty in removing cysts, but subsequent results are less favorable, for it is not sufficient to evacuate the cyst which then refills, but its wall must be dissected out; and this can rarely be done without serious injury to the brain, which may be followed by hemorrhages or by the formation of an abscess. Thus in a case operated upon by Dr. McBurney for me in January, 1895, in which headache and attacks of spasms, beginning in the arm and extending to the face, then to the body, and finally becoming general, were the chief symptoms, these symptoms having developed subsequently to a blow on the head, which had not produced any fracture, trephining over the arm area revealed the presence of a cyst containing about two drachms of clear fluid. The wall of this cyst was removed. Two days later a gradually increasing hemiplegia and mental dulness indicated the existence of compression which was found on investigation to be due to a hemorrhage that had occurred from a small vein of the pia subsequently to the operation. About eight ounces of blood clot were removed from the surface of the brain, with immediate subsidence of the mental dulness and of the hemiplegia. The patient then went on to recovery and remained well for five months, when the spasms recurred. Investigation showed that another cyst had formed at the seat of the old one. This was evacuated and the attempt was then made to secure its healing from the bottom by packing and an open dressing. This appeared to succeed, but at the end of six weeks, when only a very small sinus remained, the boy suddenly went into a condition of coma and died, and the autopsy showed a third cyst which had formed beneath the others, had invaded a large area of the brain, and had ruptured, causing death. The cases reported from Australia, of cysts that are evacuated, are largely of the hydatid variety which we do not see in America. Many of these cases recover and do not recur.

In regard to glioma, it is to be stated that in order to remove the glioma extensive excision into the brain is necessary. This need not prevent the operation, however, as vessels can be tied, either before incision is made, by means of an aneurism needle carrying a ligature deep into the brain around the tumor, or subsequent to its excision, as such vessels appear. It is a remarkable fact that even when glioma recurs it can be excised a second time or even a third time, as the cases of Von Bramann and Cleghorn prove. The probability of a return of a glioma after extirpation makes this fact important.

Tubercular tumors have been successfully removed from the brain, Krönlein having collected¹ fifteen such

¹ Archiv für klin. Chir., li., 1, 1895.

² Thacher reports that in 512 autopsies at the Presbyterian Hospital from February 1, 1893, to January 10, 1896, there were four tumors of the brain and seven abscesses of the brain. In 4,000 autopsies made by Beadles in one of the insane asylums in England there were 45 cases of tumors of the brain. In 6,177 autopsies made by Beck in Heidelberg, tumors of the brain were found fifty times. In 13,411 cases in the Nervous Department of the Vanderbilt Clinic to date, brain tumor was diagnosticated 36 times.

¹ "Zur operativen Chirurgie im Hirngeschwulste," Beiträge zur klin. Chir., xv., 25, 1895.

cases, in five of which permanent cure resulted. It must be admitted that this tumor is liable to recur, and hence the objection which Von Bergmann has made to this operation may be thought to be warranted, yet, on the other hand, there are several cases on record in which patients have lived three or more years after the removal of the tumor without any recurrence; therefore in any case in which it is evident that other organs beside the brain are not invaded by the tuberculous process operation must be considered justifiable. The question of operating for gummy tumors is also an open one. There is no question that many of these tumors can be absorbed by full antisyphilitic treatment. There are others, however, which appear to be so large as not to yield to medicines, and in these cases I do not think we should hesitate to operate, for in several cases already on record, after removal of the tumor antisyphilitic treatment previously ineffectual has resulted in complete recovery.

It is not my function to comment upon the surgical aspects of these cases, and yet my experience in brain surgery, now reaching over sixty cases of various kinds, leads me to urge the adoption of the flap operation rather than the operation of trephining, and also leads me to warn those who have not had experience from entering upon this field of surgery. I cannot but feel from the observation of many cases that it is essential to success that these operations should be done in a hospital, and should be done only by those who have had considerable practice in the performance of these operations, both upon the cadaver and upon the living subject. In this way delay is avoided; shock, which is the most dreaded feature, is obviated, and the many complicating accidents of hemorrhages, etc., are more skillfully met.

Table III. Tumors Successfully Removed.—*Central Region.*—Verco, *Trans. of Australian Congress*, 1893. Cyst hydatid evacuated. Died.—Eskridge, *Jour. Amer. Med. Assoc.*, Sept. 30, 1893. Sarcoma of fronto-parietal region, partly removed. Patient died.—Springthorp, *Australian Medical Journal*, Oct., 1893. Sarcoma removed. recovered. Glioma removed, died.—Chisholm, *Australian Medical Gazette*, 1893, p. 38. Hydatid cyst removed. Two cases, both died.—Harrison, *British Medical Journal*, Dec. 23, 1893, p. 1368. Gumma removed, but patient died.—Parry and Davenport, *Australian Medical Gazette*, 1892, p. 315. Hydatid cyst evacuated. Death on 20th day.—Pauly and Jaboulay, *Lyon Médical*, Feb. 5, 1893. Cyst. Patient died four days later.—Clegghorn, *New Zealand Medical*, Jan. 1893. Recurrent glioma operated on four times with temporary improvement.—Diller and Buchanan, *International Medical Magazine*, Sept., 1893. Cyst. Patient recovered and improved.—Brigattie Albertoni, *Revista sper. d. fren.*, 1893, p. 1. Glioma. Patient much improved thirteen months later.—Annandale, *Edinburgh Medical Journal*, April, 1894. Sarcoma. Patient recovered and was well three years later.—Vierordt and Czerny, *Fortschr. d. Med.*, 1894, No. 13, vol. xii., p. 193. Subcortical tubercular tumor in motor region. Patient recovered from first operation at which nothing was found, and from second operation one year later, at which tumor was removed; at end of one and a half years after removal of tumor patient was much improved.—Rossolimo, *Deut. Zeitschr. f. Nerv.*, vol. vi., No. 1. Cyst evacuated. Patient improved; living two months later.—Sweeney and Ancker, *North West Lancet*, July 15, 1894. Cyst evacuated. Patient recovered entirely.—Pel, *Gazette des Hôpitaux*, Jan., 1895. *Berlin. klinische Wochenschrift*, Jan. 29, 1894. Fibroid tumor removed. Patient died.—Steele, *Jour. of the Amer. Med. Assoc.*, Jan. 27, 1894. Sarcoma. One year later patient had recovered entirely.—Dana, *Journal Mental and Nervous Disease*, 1895, June. Sarcoma, partly

removed. Patient improved at end of one year.—Wood and White, *University Medical Magazine*, Jan., 1895. Subcortical glioma of arm area. Patient recovered.—Nixon, *Trans. of the Acad. of Med. of Ireland*, vol. xii., 1895. Gumma. Patient died one month later from hemorrhage.—Murray and Richardson, *Lancet*, March 16, 1895. Sarcoma. Patient recovered and was well nine months later. Riegner, *Deut. med. Woch.*, 1894, No. 23. Sarcoma removed, but symptoms remained some months later.—Grasser, *Deut. med. Zeit.*, 1895, No. 34. Cysto-sarcoma of the left motor area only partially removed without relief of the symptoms. Patient died four weeks later.—Gaykiewicz, *Neurolog. Centralbl.*, 1895, p. 181. Gumma. Patient recovered entirely.—Bremer and Carson, *American Journal of Medical Sciences*, Feb., 1895. Sarcoma. Removed in part. Patient died on seventeenth day.—Bruns, *Neurolog. Centralbl.*, 1895, p. 125. Sarcoma. Patient died of septic meningitis.—Beavor and Balance, *British Medical Journal*, Jan. 5, 1895. Sarcoma of centrum ovale under motor region operated and largely removed, July 1, 1894. In November the patient was alive and improved.—Gibson, *Lancet*, Dec. 14, 1895. Glio-sarcoma, recovery.—Horsley, *Clinical Journal*, Feb. 13, 1895. Tumor. Recovery six months later.—Roth, *Berlin. klinische Wochenschrift*, 1895, No. 41. Tumor. Patient recovered entirely.—Krönlein, *Beiträge zur klinischen Chirurgie*, xv., 251, Dec., 1895. Tubercular tumor. Patient recovered entirely.—Mya e Cadevella, *Il Policlinico*, March, 1894. Cyst removed. Complete recovery. Delorme et Schwartz, *Bul. d. l. Soc. d. Chir.*, Paris, April, 1895. Tumor removed. Patient improved.

Temporal Region.—Nicholaysen, *Annals of Surgery*, July, 1893. Sarcoma, temporal region. Recovery.

Parietal Region.—Colquhoun, *New Zealand Medical Journal*, July, 1890. Sarcoma, parietal region. Patient recovered from operation.—Rose, *Medical Press and Circular*, February 14, 1894. Sarcoma, parietal area, only partially removed. Patient died.—Starr and McCosh, *American Journal of the Medical Sciences*, November, 1894. Angioma, parietal area, removed. Patient recovered entirely. Is now well.

Occipital Region.—Rodgers, *Medical Times and Register*, 1888, ii., 343. Glio-sarcoma, occipital region, removed. Patient recovered, but symptoms remained.

Region not Stated.—Esteves, *Buenos Ayres Semane Medical*, 1894, May 17th. Cyst removed. Patient recovered.—Horsley, *British Medical Journal*, December 23, 1893. Tubercular tumor, found, removed. Patient lived two years. No return of brain symptoms.

Cerebellum.—Macewen, *British Medical Journal*, December 23, 1893. Three tuberculous tumors of cerebellum. Patients were much improved, but tumors recurred and caused death after some months.—Parry, R. H., *Glasgow Medical Journal*, July, 1893. Tumor of cerebellum partly removed. Child died.—Hermanidas, *Neurologisches Centralblatt*, 1895, p. 181. Tumor of cerebellum removed. Patient improved. Two tumors of the cerebellum found and removed. Patients both died.—Stewart and Annandale, *Edinburgh Hospital Reports*, 1895. Sarcoma, right cerebellar lobe. Patient much improved two months later.—Munn, *International Journal of Surgery*, February, 1895. Tumor of the cerebellum found but not entirely removed. Patient died the next day.

Table IV. Tumors Trephined for, Found but not Removed.—*Central Region.*—Horsley, *British Medical Journal*, December 23d, 1893. Fibroma, motor zone, too large for removal. Death.—Bruzeliuss and Berg, *Centralbl. für Nerven.*, 1895, p. 529. Glioma of the central convolutions. Not removed. Patient died two months later.—Nicholson, *British*

Medical Journal, December 23, 1839. Sarcoma of motor area, could not be removed and patient died.—Starr and McBurney. Glioma of central area too extensive and vascular for removal. Patient died ten days after operation.

Table V. Tumors Trephined for but Not Found.
—*Frontal Region*.—Chipault, *Revue Névrologique*, 1893, p. 149. Glioma, frontal subcortical. Not found at operation. Died.—Fagnet and Lanne-longue, *Mercredi Méd.*, 1895, No. 12. Right second frontal convolutions, subcortical gumma, trephined over motor region, died within a few days of operation.—Aldibert, *Revue de Chir.*, 1895, No. 2. Tumor of the first and second frontal convolutions. Trephining done over Rolandic region. Death three months after the operation.—Hernandias, *Neurolog. Centralbl.*, 1895, p. 181. Tumor of the second frontal convolution supposed to be cerebellar. Patient died soon after operation.

—*Parietal Region*.—Walton and Richardson, *American Journal of the Medical Sciences*, December 18, 1893. Aphasia. Tumor located in left parietal region not found at operation. Patient lived two months. Some relief of general symptoms for two weeks. At autopsy sarcoma at junction of parietal and occipital areas.—Horsley, *British Medical Journal*, December 23, 1893. Tumor not found, but trephining in parietal region relieved symptoms. Died two years later; no tumor found at autopsy.—Gibson, *Lancet*, December 14, 1895. Glioma of corpora striata, not found. Died.—Schlesinger, *Neurolog. Centralbl.*, 1895, p. 702. Trephined over the motor region. No tumor found. Patient living two months after the operation.—Sanger, *Neurolog. Centralbl.*, 1895, No. 10. Tumor of the inferior parietal lobule, trephining over motor region. Patient died seven months after operation.—Starr and McBurney, sarcoma of centrum ovale under motor area. Patient died ten days after operation.

—*Region not Stated*.—Keen, *American Journal of the Medical Sciences*, January, February, 1894. Occipital tumor not found. Patient died four months later. Glioma of third ventricle not found. Patient died nine hours after operation. Tubercular tumor, motor area, not found. Patient died seven months later.

Transmission of Tubercle Bacilli.—Drs. Baraud and Rénon reported to the Société de Biologie of Paris, in June, 1895, that they had investigated the question of the direct transmissibility of the tubercle bacillus of Koch, through the placenta, to the human foetus. In five cases they took a quantity of blood from the umbilical vein and injected it under the skin of the abdomens of guinea pigs, immediately after the birth of the child. In three of these cases the guinea pigs did not become tuberculous, while in two they did. In the first case the mother was in the third stage of phthisis, the sputa containing bacilli. There were no lesions of the placenta present, apparently. The guinea pig which was injected developed a chancreous ulcer at the point of inoculation, and died with tuberculosis of the liver and spleen at the end of two months. The bacilli were found in the spleen, pulp, and in the caseous masses of the chancreous ulcer. An autopsy performed on the still-born infant gave negative results. Three guinea pigs were injected with the juice of the pulp of the lung and liver and peritoneal serum, and two of them died. In the second case, the mother had pulmonary cavities, but no examination of the sputa was made. The child died of broncho-pneumonia on the fortieth day. The placenta presented a normal appearance. At the moment of birth, blood from the umbilical vein was injected into two guinea pigs; one pig died of generalized tuberculosis, the other lived.

THE THEORY AND TREATMENT OF RHEUMATISM.

By LOUIS FAUGÈRES BISHOP, A.M., M.D.,

NEW YORK,

CLINICAL ASSISTANT, COLLEGE OF PHYSICIANS AND SURGEONS; SECRETARY, SOCIETY OF ALUMNI, ST. LUKE'S HOSPITAL; MEMBER OF ACADEMY OF MEDICINE, ETC.

ONE approaches the subject of rheumatism with some diffidence, because there is so much about it that is obscure, and because in the advance of modern pathology rheumatism has been left behind. Still, for these very reasons it will be profitable to debate those theories which have obtained most prominence. One of these, the miasmatic theory, seems to be especially worthy of a careful consideration, though the lactic-acid theory still holds its ground.

We need also draw our lines more definitely in regard to diagnosis and differentiation of rheumatism and rheumatoid conditions. As to treatment, a curious condition of professional opinion exists. Many of those whose medical experience antedates the salicylic era, are faithful believers in that system of treatment, while a later generation of writers, including some eminent men, such as Osler, maintains that the salicylates act chiefly by relieving pain, but do not influence the duration of the disease nor prevent the occurrence of cardiac complications. The management of chronic rheumatism would also seem to afford an opportunity for mutual conference as to methods of management and their value.

Pathology and Theory.—It is a fact that rheumatism, one of the most prevailing of all affections, receives comparatively small attention from the pathological investigators. The cause of rheumatism in all its forms is extremely obscure. Often enough exposure to moisture and cold is the occasion of its beginning, but thoughtful attention to the subject leads one to the conclusion that these factors are not sufficient in the absence of a predisposing cause. Heredity as a factor in the causation of rheumatism receives daily confirmation, and when we watch particular families for a series of years, it becomes very striking. The slightly deformed fingers of the mother are the distorted fingers of the grandmother, but in an earlier stage, and the grandchild is just beginning to complain of aching joints. The constitutional nature of rheumatism is recognized in that it is believed to be a cause of diseases of the skin, throat, eye, nervous system, and, indeed, almost every tissue of the body.

Garrod and many other observers have studied the blood in rheumatism with regard to the corpuscles, but it does not seem that their conclusions are of any great value. The loss of red blood corpuscles is very rapid in the beginning of acute rheumatism, and the recovery is rapid during convalescence. The white blood corpuscles are increased in number. It is not at all clear that there is any difference between the action of the corpuscles in acute rheumatism and the changes they undergo in any other equally severe febrile disease.

Another school of pathologists is impressed with the relation between the cause of rheumatism and that of malaria. Pel, of Amsterdam, in 1890, in the *British Medical Journal*, shows, from the records of the Amsterdam Hospital, that in those years in which malarial fevers were prevailing, there was the smallest number of rheumatic cases, and vice versa.

When we decide that rheumatism is due to a blood poison, the poison may still be supposed either to arise within the system or to enter in from without. These two opposing ideas are represented by the prominent theories. If we had only chronic rheumatism to consider, or only acute rheumatism to con-

sider, it would not be so difficult for us to decide between the lactic-acid theory on the one hand, and the miasmatic and bacterial on the other, for, while the former lends itself easily to the idea that it is due to the products of malassimilation, or imperfect tissue metamorphosis, the latter presents the picture of an infectious disease. Long ago the excessive acidity of the perspiration, urine, and saliva suggested an acid as the cause. Then the theory was advanced that lactic acid accumulating in the blood caused the symptoms. They reasoned thus: The cause of this excess may, of course, be either in the increased formation or a defective elimination, or both. Lactic acid is a result of the destruction of tissue during exercise. If elimination occurs without interruption, there is no accumulation; but if the perspiration be checked or something interferes with the elimination of carbonic acid from the lungs, an accumulation may happen, and the condition leading to an acute rheumatic attack follow. Lactic acid is eliminated through the lungs after being decomposed into carbonic acid and water. Unfortunately, the chemical determination of lactic acid is a very difficult one. Had it been easy, the truth or falsity of the lactic-acid theory of rheumatism would have been more readily settled. In this instance, the backward development of chemistry is much at fault. The acid reaction of the secretions and excretions is easy enough to determine, but the difficulty of detecting the special organic element to which this is due has led to differences of results by different chemists; still, most observers are in favor of identifying lactic acid as the cause of the acid reaction of the perspiration in rheumatism.

About thirty-five years ago, B. W. Richardson, of London, conducted experiments which have become historical. His chief result was the induction of an artificial endocarditis in animals, by injection of lactic acid. Also in man the administration of lactic acid in the treatment of diabetes has been followed in a number of cases by rheumatic symptoms. The lactic-acid theory is still upheld by Richardson, as it has been for many years. He says the action of the poison in ordinary rheumatism is by direct action on the fibro-serous surfaces, for if the poison were conveyed by the blood through the coronary circulation, in the case of the heart, both sides would suffer alike, which is contrary to the observed fact, and that such poison should be looked for, not only in the arterial, but also in the venous blood. In the experiments on animals with lactic acid by which endocarditis was induced, he had an opportunity for observing such inflammation in the several stages of its progress.

William A. Haig claims that rheumatism, like gout, is due to an excess of uric acid precipitated from the blood, but those who have read Haig's book will remember that he is an enthusiast on the subject of uric acid, so we must not take his judgment without analysis. Still, Haig's uric-acid theory of rheumatism is not without plausible support. The fact that uric acid is not in excess in the urine in rheumatism is explained very plausibly by assuming that the chief predisposing causes of rheumatism diminish the alkalinity of the blood, or of the fluids of local tissues; hence the uric acid, rendered less soluble, is attracted to and made to unite in the tissues in quantity sufficient to cause pains and rheumatic inflammation, while the blood in the general circulation and the urine would yield less than is natural, because the blood has a less quantity in solution. This explanation of rheumatic pains, which Haig also applies to gout, he supports by ingenious experimentation upon the quantities of uric acid excreted under certain conditions. It would be curious, indeed, if at this late day we should revert to the ancient belief that rheumatism and gout were identical diseases. Though

this is not at all probable, there are sufficient analogies to make the comparison instructive.

The prevailing theories of rheumatism show a persistent attempt, continued year after year, to make at least acute rheumatism a bacterial disease, though there is a strong and very general adherence to the lactic-acid theory. Aside from microscopical evidence, which up to the present time is conflicting, the association of acute rheumatism with tonsillitis, the analogy between acute articular rheumatism and the joint conditions often observed in septic states, and the general appearance of the patient, all point to an infectious disease. On the other hand, the rarity of true suppuration in the joints of rheumatism, the imperceptible gradations between acute, subacute, and chronic rheumatism, the absence of a specific bacillus or coccus, the absence of contagion and inoculability, all point to a chemical, or, at least, miasmatic, rather than a bacterial cause.

The reign of bacteria in pathology has led many observers to attempt to prove that rheumatism is caused by special organisms, but up to the present time it is extremely doubtful whether any demonstration will hold. That there are micrococci present in the lesions of rheumatism has been abundantly shown, but that they are the cause of the disease remains to be demonstrated.

In studying rheumatism from the theoretical point of view, after reading and carefully considering the literature of the subject, it was rather a surprise to find that the miasmatic theory was the one that seemed most tenable. The bacteriological reports do not seem at all convincing, and in every respect the course of the disease would lead us to look for an organism more of the type of that of malaria. The long and sluggish course in its chronic and subacute form, its fearful severity in some of its acute attacks, make a close analogy to the action of plasmodium malariae. This view is more easily held if we distinguish between the action of the rheumatic poison and its chronic tissue effects. Suppose that the body is at some time invaded, or, if already invaded, it sometimes becomes susceptible. This germ may be active at times, and at other times quiescent, but the thickening of the joints and the chronic inflammation of the tissues will continue between the attacks to a degree depending upon resistance and the recuperative power of the individual. The miasmatic theory can easily be brought in line with the lactic-acid manifestations. The formation of lactic acid has always been spoken of as an accompaniment of rheumatism, of which it may or may not be the cause. It is easy to suppose that the lactic acid is a product of the life or activity of the miasmatic organism, which we suppose to cause a disease, or, as it is more in line with experiment, that it is the result of increased metamorphosis of muscular tissue due to the disease. The fact that this organism has so far escaped our vision is no more surprising than that a similar organism, which is probably the cause of cancer, has likewise defied certain identification. The analogy between rheumatism and gout is not close enough to lead us to the necessity of predicated a similar cause for that disease. Gout bears all the marks of a nutrition disorder, while rheumatism bears many indications of an infectious disease.

Varieties.—What impresses one in the clinical and literary study of rheumatism is that under this name there are included probably a considerable number of different pathological entities, and yet at the present time it is not at all easy to know just where the lines of demarcation are to fall which will finally differentiate them.

A noted rheumatic charlatan is in the habit of telling his patients that there are sixty-four varieties.

It is probable that there is more than one disease included under the name of rheumatism, but we need not suppose so many different varieties, since differences of structure, age, and character of attack will explain nearly all the kinds. Mixed cases do occur, however. Thus, in a case recently brought under my care, the patient had distinct rheumatic family history. He was subject to attacks of articular rheumatism of the typical ordinary variety, but in addition he had an equally typical gonorrhœal arthritis, affecting the joints of the feet, with a characteristic location in the bursa under the tendo Achillis.

Several years ago I heard Dr. Lyman, of Chicago, read a paper, at a meeting of the Association of American Physicians, in Washington, in which he described what he called gastro-enteric rheumatism; that is, rheumatic pains which were caused by errors of digestion, and probably depending upon the absorption of some substance caused thereby. This is, of course, a misuse of the term "rheumatism," and I quote it to illustrate the fact that the name rheumatism is used too often* as synonymous with pain in the extremities. Likewise it is an error to put down hastily as rheumatism every joint disease. Nearly every case of tuberculous disease of the joints is at first supposed to be rheumatic, and the same is true of many cases of neuritis.

A clinical picture of acute articular rheumatism is, of course, extremely characteristic. We find our patient with high temperature which has come on suddenly, with one or more joints extremely painful, so that the patient dreads the slightest movement. Very soon other joints are involved, and the case becomes fully developed.

Subacute rheumatism is the form, however, most frequently coming to us for treatment. Acute articular rheumatism is not numerically very common. The cases are so severe, and the course so prolonged, that we get the impression that we have a great many more than we really have. When we come to count our histories, we will always be surprised to note how few the cases are, as compared with the impression they have left upon our minds. The very chronic forms do not come to our notice very often, as compared with their number, because, unfortunately, most of these patients have lost faith in our ability to help them. So it is that the subacute cases make up the bulk of our rheumatic experience. The subacute form follows the type of the acute, but there is less fever, fewer joints are involved, and there is a greater tendency for the disease to become chronic.

Muscular rheumatism has of late years developed a good deal of discussion as to its true nature. Its clinical symptoms are familiar enough. It attacks usually certain groups of muscles, causing lumbago when in the loins, torticollis when in the neck, pleurodynia when in the intercostal muscles. It would seem that differences of opinion as to its real nature often rest upon an actual difference in cases. It has been regarded by some as an inflammation of muscular tissue; by others as neuralgia of the smaller nerve endings; by others as a rheumatic affection involving the fibrous structure connected with the muscles. The last, which is the oldest theory, is probably often the true one.

Complications.—The most frequent and at the same time the most dangerous complication of rheumatism is the involvement of the heart. Indeed, it is this complication which raises apparently insignificant attacks to a high degree of importance. Unfortunately, the risks of involvement of the heart are not always in proportion to the apparent severity of the disease, and the only safe rule is to treat all cases of acute rheumatism as if the heart were already involved. In rheumatism the heart acts very much like a joint, but

with this disadvantage, that it is a joint that cannot be put at rest. But by confinement in bed, in a recumbent position, we can lessen the strain and thus reach a comparative quiet of the organ. It would seem that the alkaline treatment would diminish the frequency of endocarditis, and, indeed, this is my feeling in the matter. By giving alkalies until the urine is alkaline and maintaining it so, we are certainly not doing any harm. However, the pathological anatomy of endocarditis is not such that we could expect too much from this very slight change in the composition of the blood bathing the valves. It is not an ulcerative endocarditis. The valves may be rough enough to cause collections of fibrin from the blood, such as are called vegetations, but there is usually no solution of the continuity of the covering of the valves. The theory that the cause of endocarditis is a poison acting directly from the blood upon the valves is not tenable, in spite of the classical experiments of Richardson. Endocarditis may occur after the inflammation of the joints has to a great degree subsided. A comparatively safe rule is to keep a rheumatic patient in bed for one week after the disappearance of pain from the joints, and to insist upon the wearing of woollen underclothing. Even this does not exempt every case from the late occurrence of cardiac inflammation. I remember a case which made a very strong impression at the time of its occurrence. A young woman had an attack of acute articular rheumatism, during which daily examination of the heart did not suggest the existence of endocarditis. She was kept in bed according to the above rule, until the pain had been absent for a week, and then allowed to move about her room. About the tenth day after the disappearance of joint symptoms, attention was called to her heart by dyspnea and pain. She had developed a very extensive endocarditis and pericarditis.

Pericarditis is not so frequent as endocarditis, but is more frequent in connection with rheumatism than with any other disease.

Pleurisy is not very common in rheumatism, though, on the other hand, the worst cases of pleurisy that we see may be rheumatic in origin. When there comes to our notice a patient suffering with pleurisy affecting both pleurae together with pericarditis and endocarditis, we can presuppose rheumatism as the cause. I remember such a case, in which the pleurisy and cardiac disease occurred with tremendous severity after joint symptoms so slight that they had not attracted the particular attention of the patient. This patient had effusions into both pleurae and into the pericardium, so that alternate withdrawals of fluid from the chests were necessary to give sufficient breathing-space. He finally made a good recovery.

The diagnosis of endocarditis is not the simple matter that one might suppose. There may be in the course of rheumatism murmurs produced by other causes than inflammation of the valves, and, on the other hand, post-mortem examination frequently shows the presence of endocarditis which has given no sign during life. Of course, when the disease is very marked there is no difficulty, but statistics of the frequency of endocarditis are very misleading. Pericarditis is not so common as endocarditis, but its diagnosis is, perhaps, more certain. Its signs are characteristic, and presence of effusion in the pericardial sac when this takes place is easily enough appreciated. During the course of rheumatism the cardiac complications usually require but little treatment. The bad effects come after weeks or months, from the interruption of the functions of the circulation, due to a gradually increasing deformity of the valves. Pneumonia may occur, but not more frequently than in other equally severe acute diseases. Cerebral complications occur in a certain number of cases of rheuma-

tism. It may cause simply delirium during the febrile stage of the disease, or it may occur later, in which case there may be doubt whether it is due entirely to the disease, or to the effect of the salicylate treatment. A certain number of cases of acute rheumatism are followed by mental derangement, which may last for a good while after the termination of the disease.

Treatment.—A great advantage of the miasmatic theory of rheumatism is that it gives us a definite and hopeful hypothesis upon which to conduct our treatment. When we meet a case of malaria we are in the habit of administering a sufficient quantity of quinine to render innocuous the malarial organism. We do not stop at a few grains, but we give enough to accomplish our purpose. In chronic malaria our efforts are not nearly so successful as in acute attacks. For rheumatism we have no antidote so good as quinine in malaria, but we have one which approaches this drug in its mode of action. Salicylic acid has an antirheumatic action, approaching in kind, if not in degree, the action of quinine in malaria. In the presence of an acute attack of rheumatism, we should give this drug in one of its forms, either salicin or oil of wintergreen, or fresh salicylate of sodium, in sufficient quantities to relieve the pain and bring down the temperature. The salicylate has not the power of bringing the local inflammation to an immediate end, but it seems to have the power of modifying the action of the rheumatic poison. Our chief failure is that we do not give enough of the drug, either from a lack of appreciation of the necessity, or because some patients cannot stand it. Salicylic acid is not all that could be desired as an antirheumatic drug, but it seems very probable that since its introduction and its almost universal use the severity of acute rheumatic conditions has been a good deal modified. It seems to me that even within my recollection the popular fear of so-called "inflammatory rheumatism" has also become a great deal less. Many careful observers concur in the belief that the salicylates do not protect the heart. On the other hand, the alkalies are quite uniformly believed to do so. The mistake usually made in the administration of alkalies is in ordering too definite an amount. I have seen a great many cases of articular rheumatism treated according to a regular formula. It was a mixture of citrate of potash and acetate of potash, of which a certain number of grains were given at certain intervals. This is not the best way of giving alkalies. It is much better to lay in a good supply of bicarbonate of sodium, and give this persistently in drachm doses as often as practicable, until the urine becomes alkaline. We can give other alkalies in combination if we wish, but the main point to remember is the importance of influencing the reaction of the urine. Bicarbonate of sodium is so familiar a substance that it is easy to get the patient to take a sufficient amount.

The Treatment of Chronic Rheumatism.—The treatment of chronic rheumatism has been rendered even worse as an opprobrium medicorum, by having been confounded with the treatment of so many other local conditions. The first step is to form a clear notion as to the particular case. How much is it an arthritis of non-rheumatic origin? How much of it is gout? How much of the pain is due to a local complicating neuritis? If the case is rheumatism, have the ordinary established methods been fairly tried? Several times it has been surprising to see a case of the most chronic rheumatism yield to the administration of salicin when given in sufficient doses. The routine treatment in dispensaries is to give a rheumatic mixture in small quantities, three times in a day, thus ruining the reputation of the mixture, and not doing the patient any good. Twenty grains of salicin every two

hours until there is relief of pain, and then continue twenty grains three times, is an average plan of procedure. Attention to diet is also important, but the disease is one of such long duration that very strict rules cannot be adhered to; however, there are certain things that can be avoided. We should avoid overtaxing the digestion. Carbohydrates, such as potatoes, should be limited, and, on the other hand, the proteids should be of the easily digested kind. Milk is a very good food for rheumatics, and if taken in a proper manner, can usually be well borne. Cod-liver oil is often extremely beneficial as an alterative in these cases.

But the picture of chronic rheumatism is a composite one. We have two sets of signs and symptoms. The one set consists of chronic thickening of structures of the joints, with the deformity, contractures, pain, and disability due to this cause. Secondly, there may be pains and inflammations due to rheumatic poison circulating in the blood at particular times. The latter suggests the importance, as recommended above, of applying to all cases of chronic rheumatism, for a time at least, the active treatment which we find useful in acute rheumatism, since it is impossible to say at any particular time how much of the pain is due to chronic tissue changes, and how much is due to the original rheumatism still acting. The absence of any degree of fever is a strong argument against the presence of an active rheumatic condition, but in the investigation of an unfamiliar case even this should not prevent a study of the effect of the use of salicin in sufficient quantities. For the relief of pains and inflammation in chronically thickened tissues and deformed joints, local treatment is necessary. In the treatment of chronic rheumatism we must give hydrotherapy and massage an important place when possible. These are best carried out at some watering-place, where they can be combined with the internal use of large quantities of water. Where there is impairment of movement and stiffness of a joint, the case must not be considered hopeless. Very many cases have been relieved by massage, passive motion, and even the forcible breaking up of adhesions. This, of course, must be accomplished with proper judgment.

Conclusion.—Hence we see that the miasmatic theory of rheumatism, in the absence of a positive discovery of an organism, affords the best working theory. We see that the severity of acute articular rheumatism has been modified in recent times, and we are justified in the supposition that this is due to the introduction of salicylic acid in its treatment. We see that in certain cases of chronic rheumatism the effect of the salicylates is satisfactory, and that these are cases in which the rheumatic poison is still acting, but that we cannot by this means control conditions due to chronic tissue effects of a previously existing rheumatic inflammation. We have purposely avoided a multiplicity of therapeutic suggestions, hoping that these will be brought out in definite form in the discussion.

30 WEST THIRTY-SIXTH STREET.

Medical Practitioners in Russia.—There were, up to July 1st, in all Russia 15,740 qualified medical men and women, 310 of whom did not practise. This gives about one doctor to 8,000 persons throughout the empire, but as the overwhelming majority of the doctors are resident in towns, while the urban population of Russia is only about fourteen per cent. of the whole, some idea may be formed of the amount of medical aid available for the peasant. Of the physicians enumerated twenty per cent. are military or naval surgeons. The women practising medicine number 553, about 1 in 30 of the total number of physicians.

ENDOMETRITIS.

BY JAMES E. FREE, M.D.,

BILLINGS, MONTANA.

A KNOWLEDGE of the minute anatomy of the female organs of generation is of special importance to the practitioner when treatment of their diseases is undertaken. The uterus is principally a big muscle lined on its surface with a mucous membrane. A muscle's business in life is to contract. Rupture of the uterus is one of the consequences of too vigorous action. This possibility is an index pointing to the fact that damage may be done in childbirth which may lead to inflammation of various grades in the organ afterward. Repair of ordinary accidents and injuries is usually a quick process in the parturient uterus. At this time the uterine muscular tissue is enormously hypertrophied. It is organized so that it can disappear rapidly afterward. At term the development of the uterus can go no further. Resistance of the organs of the body to the encroachments of the pregnant uterus, expressed by reflex impulses, is the reason for the approach of labor. Territorial acquisition must now halt. The lungs, liver, kidneys, and bladder unite to demand the enforcement of the Monroe doctrine, and the administration issues its ultimatum. After delivery, the mushroom tissue must disappear by waste metamorphosis. The placenta cuts considerable of a figure in the nourishment of the uterus, as well as of the child. When it has been removed, there is death of structure by starvation. Body heat keeps the dead elements in a liquid state, ready to be hurried out of the organ as rapidly as possible. An interference with excretory function means that there will be retained in the body a mass of material ripe for decomposition. Besides, the retention of this matter forces nature to hand it out to the various structures for nourishment, but it has no food value and is in the way of better food. A septicæmia may be caused in this way without the intervention of germs. A putrefactive change cannot stand still. Leucocytes undergo fatty degeneration; chemical action murders some outright. And so the process of multiplication will go on until serious dangers are threatened. Antisepsis, by establishing a local diaphoresis through the uterine mucous membrane, will relieve the engorged tissues, and sometimes cause an abnormal temperature to drop. High temperature, pus formation, and the various results of inflammatory action, radiating from a uterus crippled by traumatism, will carry off the victim in short order.

The mucous membrane of the uterus must be extra tough and elastic, or it could not tolerate the pressure of childbirth. Other mucous surfaces, if subjected to a tithe of such severe handling, would rebel vigorously. An accident of childbirth might be paralysis, if the uterus were built that way. It seems probable that this feminine organ is side tracked from the main line, so as to escape the burden of responsibility for dead nerve force. Still it easily stands at the head of the list when it comes to accumulating stores of human electricity. Plausible explanation of infantile reproductive organs, sterility, and various malformations are thus knocked in the head.

There is a large amount of mucous tissue ready to be involved in an endometritis. Beginning with the ovarian end of the system, and coming toward the os vaginæ, there is a large square surface, in feet and inches, to be protected. An endometritis is not confined to any particular period. Ease of communication with the outer world has much to do with the disease. The half-grown girl who is struggling to establish her menstrual function may have a catarrhal endometritis which keeps her puny and headachy.

Such cases often occur in school girls who need glasses for defective sight. If properly treated early in the disease they are spared a lifelong martyrdom to the "whites." Again, the discharge may only be the expression of active development. The growing uterine tissue calls for a large supply of constructive material and effort to use it results in a waste from the mucous surface. Healthy granulating surfaces pour out this building material in the same way when it reaches the peripheral boundary. It is unable to make the return trip, owing to the pressure exerted by the heart. The new force of puberty transmitted along the nervous tracts is at the bottom of this activity. The medical philosopher can find illustrations of nerve impulses, causing functional waste, at his back door. Here is a young rooster, standing on the fence post, conscious of a new faculty. He crows fifteen times in succession, and next day has a typical case of preacher's sore throat.

The sexual function has something to do with the establishment and maintenance of an endometritis. Too much and too long-continued congestion leads to chronic hyperæmia and inflammation. Hypersecretion is the evidence that the mucous membrane is infiltrated with lymph and œdematous. This inflammatory product is constantly making pressure on the nervous apparatus. An abnormal quantity of blood is also kept streaming through the tissues, which helps to aggravate the peripheral nerve filaments; and they in turn respond by stimulating the gland cells to constant secretion. Prostitutes after a "busy" season furnish examples of mild endometritis. All mucous surfaces secrete a constant product. In the case of the conjunctivæ the tears carry off the mucus, but if an inflammatory process is lighted up the increase of the secretion becomes so great that it acts as an irritant. The nasal membrane owns a chemical laboratory and works it day and night. When the product accumulates and interferes with respiration, the handkerchief, that septic abomination, is brought into play. Mucus seems to have a digestive action. It is not only to furnish a lubricant that it is poured out so freely, but also to act as a germicide.

The uterus is tucked safely away at the end of a sort of stovepipe. It is meant to be out of harm's way, and at the same time to be accessible for all practical purposes. Say that an inflammatory action travels up the vagina to involve the uterus. So long as there is a vent for the discharge, the matter may not be serious. If the trouble should extend into the Fallopian tubes, more serious complications arise and shine. Suppose a spermatozoon, carrying a gonococcus, obtain an entrance into this holy place; the conditions may be present which will lead to septic disease and degeneration of the ovary.

Treatment.—The treatment of an endometritis depends upon where it was born, how it has been raised, and who its relatives are. A disease of the uterus comes nearer to being an outsider than anything met with in the body. Prognosticating uterine complaints is not always easy. The crack of nature's rifle is the only unerring guide. Glandular elements are more abundant in the endometrium than in any mucous tissue in the body. Its epithelial lining extends down into the glands themselves, furnishing thousands of little suckers ready to snap at the chance to convey poison to the deeper structures. An endometrium which is the choice location for a pathological process is usually so because it is the surface which communicates with the world, the flesh, and the devil. The inflamed membrane is a menace and an incubus to its alma mater, just as a tubercle in a lung, or a phlyctenular spot on the cornea, may be the hooks to drag out respiration and sight. The main object in treatment is to remove the endometrium as completely as

the bark can be peeled from a tree. Not by the same heroic method, however. It is not so hard to do on the instalment plan as it sounds. Menstruation goes to show that shedding the membrane is at least a partial success each month. To make the uterus do by art what it is in the habit of doing by nature is the problem. Altered nerve force and better circulatory arrangements must be obtained. To meet these indications means to bring about contracted gland mouths, lessened cell activity, and better ways of removing the products of metamorphosis. An unobstructed supply of blood to the endometrium must be secured. This suggests the importance of the heart's action. Digitalis, that prince in the house of the heart, has been found to lend a helping hand. Treatment is to be divided, like an army, into divisions, and it is not always necessary in battle to use the full strength of the organization. Where a campaign is going on in the wilderness even, the reserve corps of the *materia medica* will not always save the day. If Solomon had been a gynecologist he would have had plenty of practice at home, and he could have answered his famous inquiry, Where shall wisdom be found? in one word, Antisepsis. Escharotics are sure death to germs, but they are too destructive of valuable tissue at times. The curette should always have antiseptic precautions attached. Where the curette has been used it is an unpardonable antiseptic sin to fail to wash out the débris thoroughly. It is not a soft job by any means, as anybody who has used the curette on the tough walls of the uterus can testify. Recamier's instrument can be used with considerable force on the Montana uterus; and the little devil has about the same attributes the world over.

Combined with these household remedies are others of minor importance. Every country practitioner gathers a sheaf of them with his experience, and usually reaches the conclusion, before he reaches the end of his journey, that success depends almost wholly on their entering into the case. If this were not so many a consultation would be a barren fig-tree. Time of performance of some operations is often regarded as of critical importance. Here is one of the beautiful possibilities where the operator is not too busy. For instance, if the object to be obtained is a rejuvenated membrane, the time to use the curette might be just before the period when the menstrual function is doing its level best to renew the organ's youth. Add to the time element new surroundings, new methods of exercise, and new bill of fare, and the prospects for success have an upward tendency.

Bicycle riding is forging to the front as an expedient in mild endometritis. It is what might be called the blue-blooded Rex. The benefit derived from its use is not due to giving the calf of the leg extra work, but it depends upon a peculiar tonic motion to the pelvic structures, caused by the springiness of tire and saddle. This motion, in combination with exhilarated respiration, supplies more oxygen to the tissues, and relieves congestion and sluggish circulation.

A combination of strychnine and atropine frequently has a beneficial action on a catarrhal endometritis. Its effect on alcoholic gastric catarrh is well known. The stomach is a primary, secondary, and tertiary sufferer from the bibulous habit. A course of treatment with the above-mentioned remedies usually leaves the ex-inebriate in an improved condition. His appetite is good, so is digestion. The result of the hypodermic method has been to stimulate the nervous system from a new angle. The arterioles are contracted, vasomotor function has been regulated. Extra nerve force, due to the use of strychnine and atropine, is met by capillary resistance. Stronger heart action moves the blood on its circuit. Cell function

feels the different conditions. Large quantities of a digestive fluid are poured out. Some of the nervous energy which should be used at other points is recklessly expended in the stomach. Gastric juice which is secreted under such high pressure may be deficient in some of its constituents. Whether or not it has the right proportion of the digestive ferment and of hydrochloric acid is questionable. The characteristic dryness of the throat and mouth, caused by the atropine, gives a clew to what has taken place in the stomach. A halt has been called on the leakage of gastric juice. Various drugs check the flow of secretion from mucous surfaces. There is morphine for example. It turns the key on every gland in the body, but its *modus medendi* is the opposite of atropine. The latter seems to be possessed of physiologic tact. It causes the peripheral nerve filaments to exert a drawing-string motion on the mouths of the glands. Elaboration of secretion is also retarded.

Where strychnine and atropine are used in a case of endometritis there is a spot of inflammation set up by the hypodermic injection. This is in effect counter-irritation, when continued for several weeks, and might be of as much value as a seton or scarification. In a few days the patient will say her leucorrhœa is diminishing, and it shortly subsides entirely. Then comes the tug of war, in maintaining the mucous membrane in the condition which secures the cessation of the discharge. Hydrotherapy offers us valuable aid at this juncture. Each morning the patient gets her hypodermic injection of strychnine and atropine, and at night is treated to a cold salt-water sponge bath, followed by brisk rubbing with Turkish towels. The tonic effect on the circulatory system is marked, and at the same time an oblique sedative action is produced on the nervous system, which means sleep. Not only does this plan build up bodily vigor by securing rest and improved appetite and digestion, but it does something more, which is of importance to women, namely: it increases personal beauty. Semi-invalids do not have the ambition needed to keep the skin in a healthy condition. Filth anywhere may become the resting-place for germs which threaten life. The skin and clothing ought to be as nearly aseptic as possible. Half the world does not know how seldom the other half takes a bath. "Oh, that the world would wash itself!" is the cry of the antiseptic reformer.

Why Women Live Longer than Men.—In the forty-ninth registration report of Massachusetts the compiler presents the statistics of 203 persons who were reported as having died during the ten years (1881-90) at the age of one hundred and over. Of this number, 153, or 75.4 per cent., were females. By the State census of 1885 the number of females living over eighty years of age was nearly double that of males. The greater exposure of men to accidents, to weather agencies, to the constant strain of business life, to the anxiety of providing for the family, all tend to shorten the life of men. The deaths by accident among men are more than threefold greater than among women, and men commit suicide in about a threefold ratio as compared with women.—*Boston Medical and Surgical Journal*.

A Member of the Imperial Family.—The most appalling misadventure befell the physician of the Emperor Rudolph the Second, who, in trying to feel his illustrious patient's pulse under the bedclothes, grasped a different part of the anatomy, and was informed of his mistake by His Majesty, in the following dignified words: "*Erras, amice, hoc est nostrum imperiale membrum.*"

SOME INVESTIGATIONS TO DETERMINE THE EFFECT UPON THE PERITONEUM OF SUCH SUBSTANCES AS ARE APT TO FIND THEIR WAY INTO THE ABDOMINAL CAVITY DURING OPERATIONS THEREON.¹

By J. W. STICKLER, M.S., M.D.,

ORANGE, N. J.

I FIRST introduced a considerable quantity of laudable pus into the peritoneal cavity of three guinea-pigs. In all the animals the abdomen was freely opened in the usual manner, in order to imitate, as far as possible, the usual surgical conditions. None of these pigs had subsequently a supranormal temperature, nor were there any indications of peritonitis or visceral inflammation.

The abdominal cavities of the next three pigs were thoroughly inoculated with fecal matter, obtained from a typhoid patient. One of the trio, forty-eight hours later, had a slight diarrhœa, but no elevation of temperature or peritonitis. The diarrhœa ceased in twenty-four hours. The other two showed nothing abnormal after the inoculation.

The abdominal cavities of the third set of pigs were inoculated with urine. The following morning they were as lively as usual, temperature was normal, and appetite good. Later, there was no local or general disturbance.

The fourth set of pigs were inoculated with perspiration, each abdominal cavity receiving about twenty drops. The perspiration was obtained from a man who was given a hot-air bath, the collection being made from the axillæ, sides of chest, and surface of abdomen. Perspiration from these regions would be as likely to cause peritoneal inflammation as if collected from the face. There was no peritonitis, septicaemia, elevation of temperature, or other disturbance.

Into the peritoneal cavities of the fifth set of pigs I introduced the various germs found in the mucus derived from the throat of a patient who had scarlatina (kindly furnished by Dr. Harvey), and those found in pus taken from a woman supposed to have tuberculous disease of the spine. There was not the slightest evidence of inflammatory or septic trouble in any of the pigs except one; that one collapsed immediately after the opening of the abdominal cavity and did not rally, dying within thirty-six hours. The post-mortem revealed an injected peritoneum, and a congested left kidney.

The five sets of pigs were all carefully examined after being killed, and not one showed the faintest evidence of any peritoneal or visceral lesion.

Allowing for any difference of susceptibility which may exist between guinea-pigs and man, it would seem from these experiments that fecal matter, pus, perspiration, urine, and such germs as have been alluded to, are not so likely to cause trouble when introduced accidentally or purposely into the abdominal cavity as has been supposed. Assuming this to be true, I should feel less concerned than before in the event of an accidental introduction of any of these substances into the abdominal cavity during an operation. At the same time I should take every precaution to keep all foreign matter out of the cavity, and, should any be introduced, I would, of course, resort to every available means to remove it.

Another accident which may occur during laparotomy is the leaving of a pair of forceps in the cavity of the abdomen. I therefore concluded to ascertain what would happen should dangerous foreign bodies find their way into this part of the body. I accordingly introduced several carpet tacks into the abdominal cavities of four guinea-pigs. In one case the in-

testine must have been punctured at the time tacks were put in, or very shortly after, for death followed twenty-four hours later. The post-mortem showed that even in that brief time the tacks had been glued to the intestines and omentum by adhesive inflammation. Some were fixed at right angles, the flat surface of the heads being next to the intestinal surface; others were attached sideways; all were held firmly in place by the plastic lymph.

The other animals were not affected adversely by these foreign bodies. When killed, three weeks later, it was found that in each animal some of the tacks were fastened to the intestines, others to the omentum, by plastic lymph, and so firmly were they fixed that it required considerable force to detach them. None of the tacks was free. There was no sign of inflammation of the parietal peritoneum. None of the pigs had a supranormal temperature.

These experiments appear to prove that foreign bodies of medium size, even though they be as sharp and dangerous as carpet tacks, may be well taken care of in the abdominal cavity by the good management and forces of nature.

Progress of Medical Science.

One Hundred and Thirty-Three Cases of Placenta Prævia.—Boss kept a record of the cases which occurred in two institutions in Breslau between April, 1884, and April, 1895. In one of the hospitals there was 1 case of placenta prævia to 216 of normal labor, in the other only 1 in 42. In 27.9 per cent. the placenta was central, in 61.6 lateral, in 10.5 marginal. The presentations were as follows: 66.2 per cent. head, 1.8 breech, 8 footling, and 24 transverse. Eight mothers out of the 133 died—5 from the effect of loss of blood and 3 from fever and exhaustion. Twenty-seven per cent. of the children were born alive. In 7 cases the tampon with expectant treatment was employed; in 9 cases rupture of the membranes, with forceps in 1; forced labor in 115; all the maternal deaths occurred in this latter class, and all cases in which combined version was used were very severe. One patient died from air in the veins nine hours after labor.—*Centralbl. f. Gynäk.*, No. 35, 1895.

Dr. Schleich's Method of Producing Local Anæsthesia.—He uses the following solution:

Rj Cocainæ muriatis.....	1.00
Morphinæ muriatis.....	.25
Sodii muriatis.....	2.00
Aquæ destillat.....	1000.00
M.	

The maximum dose is, as a rule, 50 cubic centimetres containing .05 gram or $\frac{3}{4}$ grain of cocaine. It is injected into the tissues by means of a hypodermic syringe.

Epilepsy Treated by Flechsig's Method.—The treatment consists, according to Dr. Davenport (*Amer. Jour. of Insanity*, 1895, No. 2, p. 207), of opium in one-half grain doses and increased by the same dose per day till fifteen grains are reached. Then opium is stopped and mixed bromides are substituted, thirty grains four times a day. The author concludes: (1) That the treatment does not result in recovery. (2) That it is of benefit in that it gives many of these unfortunates a gratifying respite from the attacks, and thus adds to their comfort. (3) That it is soothing and quieting to the irritable patients and exhilarating to those suffering from depression, thus relieving distressing symptoms in both cases. (4) That through the cessation of the seizures and other annoying symptoms the patient is enabled to enjoy something of life

¹ Part of Annual Address, delivered before the Orange Mountain Medical Society, January 10, 1896.

in general, and to recuperate physically, and for these reasons it is desirable to repeat the treatment at intervals of two or three months, if thereby we can obtain the results mentioned above.

Treatment of Zona.—Dr. Albert Robin claims that the eruption should be kept dry. He recommends an application which will also relieve the pain, as follows:

R Powdered starch.....	60 parts.
Zinc oxide.....	20 "
Powdered camphor.....	2 "
Powdered opium.....	1 part.

In elderly people be on guard against ulceration. The neuralgia which accompanies the eruption is treated by the following:

R Extract of datura stramonium.....	gr. $\frac{1}{2}$
Extract of gelsemium.....	gr. $\frac{1}{6}$
Extract of belladonna.....	gr. $\frac{1}{12}$

The above is made into a pill. Four a day should be taken. If not effectual, antipyrin is to be substituted. —*Bulletin Général de Thérapeutique*, 1895, 40 liv., p. 358.

Hemorrhage after Vaginal Hysterectomy.—Pichevin thinks clamp operations are attended with danger from hemorrhage. The clamp may cut through the included tissues, or the tissues may slip from the clamp. Slipping is especially liable to occur when the upper portion of the broad ligament is twisted, as it always is when it is clamped from above downward, and the stump is eventually drawn into the vagina. Cases of fatal hemorrhage, on removal of the clamps forty-eight hours after operation, have been known to occur. Some surgeons have succeeded in checking the hemorrhage with tampons, but others have been compelled to resort to celiotomy. The author advises compression of the aorta, and would use clamps only in cases of hysterectomy for pelvic suppuration, where it is impossible to draw down the uterus. [It is inferred that this writer has been unfortunate, in that his instruments must have been imperfect.]—*Gaz. Méd. de Paris*, 1895, No. 11.

Cerebral Uræmia.—Rendu considers two factors in relation to cerebral uræmia, namely: 1. A dominating toxic element caused by the failure of the diseased kidney to perform a satisfactory elimination of the débris of the organism. 2. A mechanical factor, cerebral œdema, the localization of which in motor zones may cause convulsions, either general or limited to one side, to one member, or merely to several facial muscles. In some cases the uræmia presents an apoplectic form, in others it is hemiplegic; both depend, however, on cerebral œdema. The writer thinks that uræmia causes many cases of hemiplegia ordinarily supposed to be due to hemorrhage or softening. Autopsy on a number of cases of hemiplegia showed no lesion, but this might be accounted for by the theory that the area of œdema disappeared at the moment of death.—*Jour. de Méd. et de Chir. Prat.*, July 10, 1895.

Treatment of Epididymitis.—The affected testicle should be wrapped in lint and be moistened constantly, either with lead water and opium or the following:

R Tincture of aconite,	
Tincture of opium.....	āā fl. ℥ i.
Dilute lead water,	
Water.....	āā fl. ℥ ij.

—DENNIS' *System of Surgery*.

Treatment of Syphilis.—(1) Mercury should be the foundation of the treatment; potassium iodide is a useful accessory agent of medication. (2) The mercurialization ought to be initial, prolonged, and

of sufficient dose for giving to the future a relative security. (3) The case in which the mercurial treatment has been abandoned before the end of the second year is one insufficiently treated. (4) Mercury has a preventive action against all the manifestations of the disease; the proof of this is, for example, the constantly favorable action of mercurial treatment administered with the purpose of avoiding the hereditary manifestations in the descendants of syphilitics. —DR. MOREL-LAVALLÉE, in *Revue de Thérapeutique*, 1895, No. 21, p. 651.

Gonorrhœa.—Repeated observations of the sexual organs of infected women have demonstrated the presence of gonococci in the mucous membrane of the uterus as well as in the adnexa. But hitherto these microbes have not been encountered in the muscular coat of the uterus. Dr. Madleuer, of Munich, has now, however, recorded a case of gonorrhœa in which the uterus had to be removed seven weeks after confinement, and where numerous colonies of gonococci were discovered in the muscular coat both of the cervix and fundus. The author believes that the negative results of previous examinations may have been due to the fact that the gonococci are unable to maintain a lengthy vitality in the uterine muscular structures.—*Münchener Medicinische Wochenschrift*, December 24, 1895.

Objective Tinnitus Aurium.—Under this title a case has been reported by Dr. Kauffmann, in which noises originating in the patient's ears were distinctly audible by others. The case was that of a boy, fourteen years of age, who had fallen on the back of his head. He remained unconscious for nearly two weeks. The noises were bilateral, but more distinct on the left than on the right side. The sounds were described as crackling and seemed to depend on movements of the arch of the palate. Dr. Kauffmann expresses the opinion that the noises were due to clonic spasm of the tensor veli palatini. It is stated that under appropriate treatment the tinnitus gradually subsided.—*Deutsche Medizinische Zeitung*, January 6, 1896.

Rupture of Left Lateral Ventricle.—Under this title Dr. B. Merrill Ricketts, in *Medicine* (July, 1895), reports rather an exceptional case. The patient was a boy, twelve years of age, who had had fair health up to this illness. His symptoms when Dr. Ricketts saw him on the fourteenth day were: Normal temperature; right pupil widely dilated and giving no response to light; pulse 120 to 150. The patient was very sluggish and unable to swallow. No paralysis of sensation or motion in any group of muscles. No drawing of the face to one side. There was no history of injury or ear trouble. On post-mortem there was no indication of perforation of any of the basilar bones. On removing the dura, however, a rupture of the brain substance on the under surface of the sphenotemporal lobe was noticed. The laceration extended into the left lateral ventricle, which was found to contain about two ounces of bloody serum. Both gray and white matter around the perforation was very soft. The dura was intact and there was no trace of inflammatory action. Dr. Ricketts thinks that this was a case of effusion in the ventricle, which caused a rupture of its lower wall into the sphenotemporal lobe. Dr. Ricketts also reports three cases in which he operated on the brain for epilepsy, in all of which there was some slight improvement in the condition of the patient.

Alkalinity of the Blood and Microbic Infection.—Dr. Fodor records a number of experiments showing the influence of the alkalinity of the blood on diseases

produced by micro-organisms. Four series of experiments on animals are first reported, which show clearly that, by the administration of alkalies (sodium bicarbonate by the mouth or by subcutaneous injection), the power of resistance against infection with cultures of anthrax bacilli is greatly increased. The normal alkalinity of the blood was determined by the examination of seventy-six healthy rabbits, and four experiments are reported, showing the increase in the alkalinity of the blood which occurs after the administration of sodium bicarbonate. The author then records the results of a large number of observations on the alkalinity of the blood in rabbits after infection with the bacilli of anthrax, cholera, typhoid fever, tuberculosis, and erysipelas. These observations show that in the living organism after infection with certain bacilli, there is first an increase of the alkalinity of the blood and then a diminution of the same, more or less. If the infection is fatal, the diminution of the alkalinity is marked and progressive; if not fatal, the diminution is slight, and is followed by an increase of alkalinity, which then remains high, permanently. Thus there exists a connection between the pathological action of certain bacteria and the alkalinity of the blood. Those rabbits having the greater alkalinity of the blood, as well as those in which the alkalinity of the blood is increased to a greater extent after infection, have greater power of resistance against certain infectious organisms (anthrax bacilli) than the rabbits in which the alkalinity of the blood is less. It appears, therefore, that the degree of alkalinity of the blood, as well as the power of the organism to increase this alkalinity with corresponding intensity after infection, is of essential influence upon humanity.—*British Medical Journal*.

Trichloroacetic Acid in Purulent Inflammation of the Middle Ear.—Dr. Okuneff is convinced that with this remedy one may always obtain a complete cure of chronic otorrhœa with a re-establishment of hearing. The suppuration may be quickly arrested, the offensive odor removed, and the regenerative power of the membrana tympani awakened to repair the perforation and re-establish normal audition.—*Revue de Laryngologie, etc.*

Tenneson's Acne.—Hallopeau and Macrez insist upon the difficulties which the diagnosis of this affection may present from that of pityriasis rubra pilaris. It is distinguished by the absence of localization upon the backs of the fingers, by the projection of filiform comedones, by the presence in the loins of isolated lesions presenting the same features. Bacteriological examination shows an absence of the fine bacilli pointed out by Unna as characteristic of acne vulgaris; this keratic acne thus differs essentially from it.—*La Trib. Méd.*, December 25, 1895.

The Microbe of Scurvy.—Drs. Testi and Beri have succeeded in isolating from a piece of scorbutic gum a micro-organism which they believe to be the cause of scurvy (*The British Medical Journal*). The microbe stains in all the aniline dyes, resists Gram's stain, is perfectly round, and generally united with one or more of its kind. Its culture renders gelatin fluid, and gives rise to a sawdust-like deposit. Inoculation of these cultures into guinea-pigs and rabbits gave rise to fever, and the necropsy showed hemorrhagic stains in various parts of the body, and nodules of connective-tissue new formation. Experiments were made in four cases, and in three out of the four the above-mentioned results were obtained; in the fourth case the authors attribute their negative results to the fact that the patient had improved considerably under treatment. The diplococci found by the authors

differ considerably from any that are usually present in the oral cavity of man.

Operations on the Adnexa During Pregnancy.—Dr. Delagénière reports three successful cases of cœliotomy during pregnancy (*The American Journal of the Medical Sciences*). In one the patient had an attack of peritonitis during the third month, and when this subsided an ovarian tumor was discovered on the left side, the pedicle being found to be twisted when the abdomen was opened. The cyst, which was generally though not firmly adherent, was removed, and the patient went on to full term and had a normal confinement. The second patient, five months pregnant, suffered from general abdominal pain and tenderness with tympanites and obstinate constipation. On opening the abdomen it was found that both tubes were much enlarged and contained a bloody fluid, the ovaries being nearly normal, while several coils of intestine were adherent to the uterus. The adhesions were separated and both tubes and ovaries were removed; the patient had a normal convalescence and was delivered at the usual time, the only symptom noted being a sudden attack of abdominal pain a few hours after the delivery, attended with vomiting, which lasted only a short time, and was probably due to the separation of an adhesion. In the third case a movable dermoid cyst was removed during the fifth month without interruption of the pregnancy, which concluded normally. The writer infers from his experience, that so far from pregnancy being a contraindication to ovariectomy, it is actually an urgent indication for operative interference. The prognosis as regards the continuance of pregnancy is better if the operation is uncomplicated and it is not necessary to handle the uterus.

Stone in the Stomach.—Dr. Manasse has recently observed the following case: A man, aged forty-four, complained of anorexia, headache, etc., had a coated tongue, and slight tremor. His symptoms were attributed to alcoholism, and after a month's treatment he was much improved. Later he died of rapid tuberculosis of the lungs and diaphragm. Besides this the autopsy revealed a deep chronic ulcer of the stomach situated close to the pylorus, and causing adhesion of this part of the stomach to the liver. Near the ulcer was found a calculus of flattened cylindrical form, measuring 10 cm. in length, 5 cm. in width, and 4 cm. in thickness, and weighing 75 grammes. It was very dark green in color, of a resinous appearance, showing a laminated structure. Chemical examination confirmed the view that the concretion was of a resinous material, resembling shellac. The patient was a joiner, and Manasse thought that he probably habitually drank some of the alcoholic solution of shellac used in his trade, and that the shellac, precipitated in the stomach, gave rise to the calculus. His master, when asked about it, said that the man had habitually drunk shellac polish, and that he had repeatedly warned him on that account. In this case there was only one concretion, but in Carl Friedlaender's case there were many shellac stones in the stomach and intestines, and they gave rise to fatal occlusion.—*Berliner klinische Wochenschrift*.

The Fresh-Air Treatment of Pertussis.—Dr. Ullmann is thoroughly convinced of the efficacy of the fresh-air treatment of pertussis (*The American Journal of the Medical Sciences*). For sake of comparison between the period passed out of doors and that passed in the house, he has noted, in a series of cases, the hours spent in each, and the number of paroxysms and their intervals under the two conditions. From these data he concludes that the fresh-air treatment is one

of the most efficacious, if not the only one, for the management of a case of whooping-cough. The child should pass the entire day out of doors, not only in the warm season, but even at all times of the year, provided it be not stormy. It is considered only necessary to prevent the child from running, or talking, or otherwise provoking an access of coughing. Contrary to general teaching, he advocates the open-air exposure of the patients even when there is bronchitis or broncho-pneumonia, whether consecutive to pertussis or not, the only precaution being to have the little ones well wrapped up. This plan he has practised with infants a year old, suffering from grave broncho-pneumonia. During this treatment the author employs neither a specific nor narcotics. In the presence of very grave broncho-pneumonia he prescribes spirits of camphor with an expectorant.

Acute Articular Rheumatism and Pregnancy.—

From the study of sixteen cases in which rheumatic fever occurred as a complication of pregnancy, Dr. Clivio draws certain conclusions as to the influence pregnancy has upon the rheumatism, and conversely. With regard to the course, duration, and local results of the rheumatic process in pregnant patients, the cases seen seemed to show little difference from the phenomena observed in the non-pregnant condition. At the same time, the morbid process showed a certain tendency to be protracted, and the joint most affected required rather a long time before it fully regained its functional activity. In two cases the mothers died, in both from rather uncommon complications: in one instance from endocarditis affecting in an ulcerative manner the aortic valves, in the other from cerebro-spinal meningitis. As to the influence of the rheumatism on the pregnancy, Clivio found that out of the sixteen cases four went on to labor at the full term; in three the patients left the hospital undelivered, but recovered from the rheumatic attack; six times there was premature labor; once there was an abortion, and on two occasions obstetric interference was required to free the patient from indications of urgency. Seven instances of premature labor and abortion out of a total of sixteen cases show that rheumatic fever has a very prejudicial effect on the progress of a concomitant pregnancy; but at the same time it was to be noted that there were in several of the cases circumstances (complications, etc.) which served to some extent to explain this high rate of interference with gestation. In only three cases could it be maintained that the rheumatic fever alone had put a stop to the pregnancy. With regard to evil effects arising from the use of salicylate of sodium in the treatment of these cases, Clivio does not believe that the drug injuriously affects the fetus, although Schatz has affirmed the contrary; and that it has an abortifacient action on the uterus he considers as not yet determined.—*Edinburgh Medical Journal*.

The Relation of Graves' Disease to Rheumatism.—

Dr. Mackenzie observes that quinsy and rheumatism are antecedent or coincident in a significant number of cases. Out of some forty cases he has noted quinsy in nine and acute rheumatism in five, this agreeing with the evidence of others. S. West records two cases, and remarks that they present two features of interest, viz., that they occurred in sisters, and that in each there was a history of rheumatic fever and heart lesion. In a previous report of fifty-six cases, rheumatic fever had occurred in 11 per cent. Heredity seems in many cases to have an undoubted influence on the occurrence of Graves' disease. Thus we have already alluded to two sisters, one with Graves' disease, the other with myxœdema, reported by Oppenheimer. In Mackenzie's forty cases five had

a family history with exophthalmic goitre. West's two cases were sisters. Ball, cited by Oppenheimer, reports a case of a mother and two sisters, and Oesterreicher, also cited by the same writer, has recorded a remarkable instance of a hysterical woman who had ten children, eight of whom had exophthalmic goitre. Maude reports a woman with myxœdema, whose daughter had exophthalmic goitre. Progressive muscular atrophy, in association with Graves' disease, is reported by Bathurst, though Beevor thought it might possibly be a case of pseudohypertrophic paralysis. Bryson's symptom in Graves' disease has been investigated by Patrick, who found the average chest expansion in forty cases to be 4.3 centimetres (hand grasp 43.75 kilog.), in twenty-eight other chronic diseases 4.8 per cent. (grasp 56.36 kilog.)—that is, the expansion in Graves' disease is diminished half a centimetre (the grasp 12.61 kilog.). Thus the chest expansion is diminished 10½ per cent., and the hand grasp 22½ per cent., the grasp being diminished more than twice as much as the expansion, and thus the idea that the diminished chest expansion is simply part of a diminished vitality or energy is borne out both by these figures and by the history of the individual cases. He believes that the diminished power of conveyance often observed and the occasional affection of the laryngeal muscles are quite analogous to these other findings, and are simply parts of a general myasthenia. The value of the Bryson sign thus loses its importance as a diagnostic sign of Graves' disease.—*The Hospital*.

The Question of Stitch Abscesses.—

Dr. Lauenstein has studied the cause of the stitch abscesses observed in patients after aseptic operations. He made 216 observations on different suture and ligature materials in regard to their bacteriological relations. Among these bacteria capable of development in so-called sterilized catgut were found 35 times. In 149 samples, 107 were sterilized by dry heat; but 29 were afterward found to contain bacteria capable of development. The bacillus subtilis occurred most frequently, although the micrococcus tetragenus and the staphylococcus albus were also found. The author summarizes his observations as follows (*The American Journal of the Medical Sciences*): 1. Clinical observation shows that there are cases of wound infection which have their origin in the catgut used in the operation. 2. It cannot be definitely settled in any case that the catgut was the source of infection. 3. But it can be said that the so-called sterilized catgut sold in shops contains bacteria capable of development and growth. 4. So long as this catgut is found to contain bacteria, it cannot be free from the suspicion of being the source of infection in wounds. In the discussion that followed, Kocher, of Berne, said that since 1888 he has employed silk only, and that in his goitre operations before that time he had only 35 per cent. of absolutely primary healings, while since then he has had 85 per cent. Kocher believes that the suture material should be not only aseptic, but also antiseptic. The past winter he has placed his silk in a watery solution of arsenious acid, and as a result in 35 cases has had absolute primary union.

The Treatment of Intra-abdominal Lesions.—

One of the unsettled questions in surgery is the treatment of intra-abdominal lesions, the fatality of which is notorious. We have the usual divergence of opinion, largely owing to the fact that a correct diagnosis is extremely difficult, for in these cases we find comparatively slight external evidences of injury, although the general condition of the patient is suggestive of a serious internal lesion. Deaver thinks that the majority of these cases demand abdominal section; although, except in extreme cases, he would not advise

it unless the diagnosis was tolerably certain. Chaput, Berger, and Michaux are also in favor of early intervention. Michaux regards it as certain that an exploratory laparotomy should be at once undertaken in severe contusions of the abdomen. He insists that good results can be insured only by early and rapid operation. Of six patients on whom he has operated within the first twenty-four hours none died; but of four cases in which operation was delayed to the twenty-third and twenty-sixth hour, third and seventeenth day respectively, two died. Sorge writes in a similar strain, and refers to fourteen cases of abdominal injury (stabs, gunshot wounds, contusions) in which he performed laparotomy as soon as possible, and of whom nine recovered. Battle is of opinion that operation should be resorted to if the shock is considerable or increasing, and associated with a large or increasing amount of blood in the peritoneal cavity. In favor of a more expectant plan of treatment we find Berger, Manley, and Chaput. The last-mentioned thinks that we should always abstain from intervention in cases of severe shock, unless there are such distinct symptoms of hemorrhage as to demand operation; but he considers that an operation is indicated by a previously existing shock, accompanied by abdominal pain, retraction of the abdomen, nausea, and bilious vomiting. Delorme refers to nine cases of severe contusion of the antero-lateral walls, of which two only were subjected to operation; the other seven recovered spontaneously. Bryant recorded twenty-seven cases of severe abdominal contusion treated on the expectant plan (for it was before abdominal operations were thought of in these cases), and all recovered except one. In summing up these various opinions, it seems pretty clear that except in very severe cases exploratory operations are unjustifiable. It is well known that blows on the epigastrium are capable of producing the most severe symptoms, without causing any distinct lesion; and the knowledge of this fact alone should make us cautious in too hastily deciding to operate in the presence of mere shock. Where there are symptoms of severe hemorrhage or laceration of a viscus, our course is clearly to operate without delay; but in more dubious cases we can afford to wait and see whether the symptoms are improving or getting worse—a point which can generally be decided within twenty-four hours—and then plan our treatment accordingly. Manley truly observes of these cases: "Laparotomy, serious as it is and always must be . . . does occasionally offer the only possible hope of saving life, and for such should be recommended."—*Bristol Medico-Chirurgical Journal*.

Unruptured Membranes at birth are of such rare occurrence that Forman records an instance in which delivery followed a single pain in a woman of twenty-two, pregnant for the second time.—*Journal de Méd. de Paris*.

Syphilitic Heart Disease.—At a late meeting of the Charité Aërztte of Berlin, Dr. Israel showed a specimen of this kind. During life the patient, aged forty-seven, had presented the appearances of hepatic cirrhosis. The pulse, 136, was small and irregular at first, but improved under digitalis. A systolic murmur was heard in the left second and third intercostal spaces, with an accentuated second sound. There was no clinical evidence of syphilis. Eight days after admission there was a profuse and fatal hemorrhage from the stomach. The autopsy showed the heart to be hypertrophied, but only slightly dilated. No circulatory obstruction could be proved at the mitral orifice. Islets of fibrous tissue were present at the base of the papillary muscles, and the muscles themselves had undergone fibrous changes. Fine strands of fibrous tissue were seen in the slightly

brown cardiac muscular tissue. The dilated left auricle presented peculiar appearances. The wall was rigid, with only the remains of a few yellowish-brown muscular fibres. The auricular appendix was greatly shrunken. Very irregular and easily detached excrescences were found on the inner wall of the auricle, and were specially well marked on the upper surface of the mitral valve segment. The gummatous formation in the heart muscle could only be due to syphilis. In the liver fibrous changes with the remains of gummata were found. There was induration of the uterus with chronic endometritis, also of syphilitic origin.—*Berliner klinische Wochenschrift*.

Neuralgia Cured by Resection of the Eighth Cervical.—Drs. Chipault and Demoulin report a successful case of this kind. A man of thirty-eight, otherwise in good condition, had for four years suffered from a continuous pain localized in the little finger and inner part of the hand, with exacerbations shooting along the inner border of the forearm. He had been submitted to all sorts of remedial measures without relief; among others, stretching the dorsal cutaneous branch of the ulnar and section of the same in the epitrochlear fossa. When he came under the author's observation examination showed that the hyperæsthetic zone comprised the inner surface of the little finger with the corresponding part of the hand and two strips on the arm and forearm, one and one-half centimetres wide—one anterior, the other posterior. From the researches of one of the authors it is proved that this is the exact area of cutaneous innervation from the eighth cervical. It was therefore decided to open the spinal canal. After resection of the vertebrae, nothing abnormal was found in the spinal canal or in the intervertebral foramina. The dura was then laid open and the posterior root of the right eighth cervical, with the nerve above and below, was resected between the ganglion and the cord. These adjacent nerves were resected also, because physiology teaches that section of a single root is insufficient to anæsthetize its territory. Two hours after the operation the zones of hyperæsthesia and spontaneous pains had disappeared. The patient was able to use his hand for eating soup and for writing, which had been impossible for years on account of pain. Four months after the operation the recovery still persists with no consecutive trophic troubles. On the contrary, those remaining after the resection of the ulnar nerve have disappeared. Some interesting physiologic manifestations were noticed during and after the operation, among them—electrical stimulation of the posterior roots produced a manifest vasoconstriction in their territory. The resection of these three roots caused only a slight hyperæsthesia of the arm, which disappeared in twenty-four hours.—*Journal of the American Medical Association*.

Compression of the Carotid Arteries and Senile Epilepsy.—The nature of senile epilepsy is not very well understood. Dr. Naunyn believes that cerebral anæmia may account for some of the phenomena. At any rate he has recently had three old men under observation in whom compression of the carotids would always bring on epileptiform attacks. The patients all had arteriosclerosis and feeble hearts. Carotid compression in persons without a history of epileptic seizures and without arterial changes did not produce more than temporary vertigo. But in two men over fifty years of age and having signs of arterial sclerosis, Naunyn observed loss of consciousness, a retarded pulse, and even mild convulsions, following carotid compression. Naunyn thinks that his observations, although not numerous, tend to show that senile epilepsy may be due to disturbances of circulation caused by cardiac and vascular degeneration.—*Zeitschrift für klinische Medizin*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 1, 1896.

EMERGENCY RATIONS IN ARMIES.

IN a previous issue we have alluded to certain experiments made under supervision of the commissary department of the United States Army. Compressed foods, we pointed out, were not likely to become very popular in our country, where an abundance of palatable provisions is within reach of the vast majority of all the people.

In times of actual distress, however, or in sudden emergencies, such as have recently been conjured up by prevalent war scares, questions of concentrated foods and minimum rations will have a timely interest, which under normal conditions would be wanting.

Major C. A. Woodruff, United States Army, of Washington, assistant to the commissary-general of subsistence, has made and is still making a number of experiments along these lines. This work is being done preparatory to the adoption of an emergency ration for our soldiers.

Major Woodruff, we are informed, has also received reliable reports describing the emergency rations of several foreign armies. These rations merit examination.

In France they use a compressed vegetable preparation consisting of potatoes and peptonized meat, predigested according to the Koch process. Each soldier is given four small packages of this composition, each package containing eight rations, the cost being a penny a ration. A two days' ration for the French soldier consists of hard bread, rice, salt, sugar, coffee, preserved meat, and condensed soup, weighing in all a little over four pounds and a half.

In England they have employed a compressed vegetable preparation, to be used with Chicago compressed beef as an emergency ration. A new emergency ration now in the experimental stage consists of a package about the size of an ordinary cartridge box, to be strapped to the belt. Each of these package contains in a compact form sufficient food to keep the most robust soldier in fighting trim for twenty-four hours. The constituents are soup, milk, and sugar in a dry state. Cocoa, milk, and sugar are packed in similar boxes.

The emergency ration of the German army, to be used only in extreme cases, consists of biscuit, meat, rice, coffee, and salt, packed in aluminium capsules and weighing in all four and one-fourth pounds. The

German army formerly manufactured for itself a similar ration by compressing a mixture of peameal, fat, and bacon into sausages.

The Australian soldier carries an emergency ration weighing a little over a pound and a half. This contains compressed biscuit, preserved meat and soup, salt, and tobacco.

Soup tablets and bread tablets have given satisfaction in our army, and compressed coffee and tea sweetened by saccharin are being experimented with.

The outcome of the various food experiments now making, will, it seems to us, bear watching. Natural food in bulk will never be supplanted by artificially compressed and condensed products. But reserved for actual emergencies, they will have to command attention.

THE BACTERIOLOGICAL DIAGNOSIS OF TYPHOID FEVER BY ELSNER'S METHOD.

ALTHOUGH typhoid fever is now quite generally accepted as one of the group of microbic maladies, the diagnosis of doubtful cases by bacteriological tests has not yet found its way into every-day practice. The identification of the typhoid bacilli has hitherto been beset with time-robbing difficulties. For this reason physicians have relied on the older methods of clinical diagnosis.

But it now appears that the recent observations of Dr. Elsner (referred to in the *MEDICAL RECORD* of January 25, 1896) have already received corroborative recognition from other observers.

Dr. Lazarus, of Berlin (*Deutsche Medizinische Zeitung*, January 13, 1895), has recorded a number of typical cases of typhoid fever in which the method of Elsner amply confirmed the clinical diagnosis. In every case (with one exception) forty-eight hours sufficed for the growth by culture of typhoid bacilli. Even in convalescent cases bacilli were still found, a point of practical importance according to the author, as foreshadowing the possibility of relapse. In the single case alluded to, the growth of the microbes was not complete before the end of the third day. Yet, in this instance also, the final result was a positive one.

The same author also refers to three doubtful cases in which bacterioscopy gave negative results, and in which the subsequent course of the disease showed that enteric fever was out of the question. Lazarus emphasizes the great simplicity of this method, especially as compared with the oftentimes difficult bacteriological diagnosis of cholera.

Prof. L. Brieger, of Berlin, has likewise confirmed the utility of the method of Elsner in eleven cases, published in the *Deutsche Medizinische Wochenschrift*, No. 50, 1895. In all his cases the cultures became plainly recognizable in forty-eight hours. The identity of the bacilli was further established by Pfeiffer's test, namely the power of the blood of enteric-fever patients to confer immunity against infection by typhoid bacilli.

We are informed, finally, that Elsner and others are at present utilizing this new method for purposes of

study in connection with the distribution of the bacilli in the ground and in water.

This discovery promises well for the future, and we await with interest its more complete development. Perhaps we shall soon be able to diagnose typhoid fever by bacterioscopy with the unerring promptitude that now pertains to the recognition of cholera.

THE EXCLUSION OF ENGLISH FROM THE MOSCOW CONGRESS.

WE have received an official communication from the secretary-general of the Twelfth International Medical Congress to the effect that the congress will be held in Moscow during the week beginning Thursday, August 19, 1897. Accompanying the notice is a list of rules drawn up for the congress, one only of which possesses any concern for English or American physicians, its peculiar and insulting provisions serving to destroy any further interest that otherwise might have been felt in the congress. The section referred to is numbered 21, and reads as follows: "French is recognized as the official language of the congress in all its international relations. At the general meetings the addresses may be delivered in other European languages. Papers may be read and discussed in the meetings of the sections in French, German, or Russian."

This is a solution of the vexed question of an international language, with a vengeance! We see no objection to the adoption of French as the business language of the congress, and even had this been proclaimed as the sole language for the scientific work of the meeting, although we might have doubted the wisdom of the measure, we should not have disputed the right of the committee on organization so to decide. But when the officers of a meeting purporting to be international in character deliberately exclude the most important language in the world and substitute therefor a tongue known only by individuals here and there in western Europe and in America—the most difficult and the least important of the six leading languages of Europe—they make of the congress a purely local affair, and give notice to outsiders that they are not wanted.

PRISON ASSOCIATION REPORT.

THE report of the committee of the Prison Association to inspect the penal institutions of New York City has just reached us, and contains some very radical suggestions for the improvement of our prison system. It recommends that the old Tombs Prison be razed to the ground, and a new prison be constructed as a place of detention and not of punishment. We can but hope that this change may soon be brought about, for there seems to be no question that the condition of the prisoners who are committed to that prison is more worthy of Siberia than of New York. The committee also recommends a new penitentiary and workhouse on Riker's Island, and that the present workhouse and penitentiary on Blackwell's Island be

changed and used for charitable institution, or torn down. It also objects to the confinement of more than one man in a cell of a city prison or of the penitentiary at Blackwell's Island; and suggests that the cells should be lighted by electric lights, and the inmates permitted to read for a reasonable time; that suitable rooms are sadly needed for hospital, for meals, and for religious services, and for exercise in bad weather; that water closets in cells should be removed and buckets substituted in their place. The committee advises canvas cots or hammocks in place of mattresses and straw beds which are now used and which are a constant source of impurity and contagion. Rain baths are recommended and that the prisoners be made to bathe at stated intervals. It is also considered advisable that the bakeries should be established in the penitentiary instead of at the workhouse, where they are now. It goes without saying that there is a crying need for reform in the city prisons of New York. We are only lately informed by a gentleman well qualified to judge, that he has rarely seen anything worse than the condition of the wretchedly overcrowded Tombs Prison in New York.

THE NEW PHOTOGRAPHY.

WE referred in a previous issue to the discovery by Professor Roentgen of rays of light which pass through opaque bodies, and also to some of the surgical and medical possibilities involved in this discovery. The recent telegrams from Europe show that the discovery is a genuine one, and that it has already been made use of in surgery. It should be understood that the process discovered by the Würzburg professor is not one which is exactly like photography, or, at least, does not give effects like those of the usual photographic picture, so far as we can understand the method from descriptions that have been given. A glass tube whose interior is as nearly a complete vacuum as possible, is made luminous by the passage of an electric current, the cathode or negative pole of the current being the one which brings out the luminosity. This luminous vacuum contains an especial kind of light which has the property of passing through some opaque bodies but not through others. Certain metals, for example, and the bones of the body are opaque to this light, but wood and flesh are not; consequently, the light from this tube when thrown upon the outstretched hand, for instance, passes through all but the bones, and casts a shadow of the skeleton of the hand upon a sensitive plate prepared to receive it. In the same way, a metal object, like a bullet, implanted in the soft tissues of the arm or leg, can be photographed, or, at least, its outline brought out. But after all, these are not so much photographs apparently, as silhouettes. Assuming that the bones are, as described, opaque to this current, we do not see that the new photography can be very largely applied in surgery, since it could not detect the presence of bullets in the brain, and it would evidently be a very confusing and difficult task to photograph a bullet of the thoracic or abdominal cavity, where the bony surroundings would

cut off the larger part of the rays of light. However, the discovery is still in its infancy, and it is possible that modifications of the process may be made which will be of immense service in surgery and medicine.

THE HEALTH BOARD AND THE PREVENTION OF DISEASE.

THE Board of Health of this city has made another advance in its work toward the prevention of disease. It recently adopted an amendment to the Sanitary Code, providing for licensing milk dealers. This amendment provides that no milk shall be received, held, kept, offered for sale, or delivered in the city of New York, without a permit in writing from the Board of Health. All dealers in milk will have to obtain these permits, and such permits will be given only to persons whose dairies have been carefully inspected. The Board, as we have previously stated, has also adopted an anti-expectoration resolution. This requires that notices be posted in all public places, warning persons against expectorating on the floors, and municipal authorities and railroad companies will be required to provide proper receptacles for expectoration which, must be kept thoroughly clean. A further amendment to the Code has been proposed, prohibiting the common use of knives, forks, and spoons on free-lunch counters, and also prohibiting the use of roller towels in the lavatories of saloons, restaurants, and other public places. The provisions of this resolution, if carried out, will give the death blow to the free-lunch counter. Some years ago procedures such as those we have just referred to on the part of the Board of Health would have called out a great deal of ridicule and violent opposition. The sanitary education of the public, however, has proceeded so rapidly that measures which are really somewhat radical now awaken only favorable comment. It is a great tribute to the intelligence and receptiveness of the people of this metropolis.

Dinner to Dr. John Byrne, of Brooklyn.—The Brooklyn Gynecological Society tendered to John Byrne, M.D., M.R.C.S., its first president, a complimentary dinner at the Union League Club on the evening of January 23d. Representatives from the different medical societies of New York and Brooklyn, together with leading citizens, paid just tribute to the distinguished guest. Speeches were made by A. J. C. Skene, Gen. Stewart L. Woodford, Dr. Egbert H. Grandin, Dr. Landon Carter Gray, Dr. H. T. Hanks, Dr. George McNaughton, Dr. William Maddren, William Cullen Bryant, Dr. W. B. Chase, District Attorney Foster L. Backus, Dr. J. Hoop, Dr. William H. Skene, and Dr. W. J. Corcoran. Dr. Byrne, after feelingly thanking the members of the Brooklyn Gynecological Society for the honor they had conferred upon him, gave a humorous yet truthful history of the early struggles of gynecology. Dr. A. Ross Matheson presided and the following committee had the affair in charge: Drs. W. B. Chase, A. J. C. Skene, Frank Baldwin, and J. C. MacEvitt.

News of the Week.

Obituary Notes.—DR. THOMAS BECKETT, of Albany, died in that city on January 8th, of pneumonia, after a brief illness. He was a graduate of the Albany Medical School in 1861. DR. JOHN P. GRUWELL, said to be the oldest graduate of the Medical Department of the University of Pennsylvania, died at Alliance, Ohio, on January 20th, aged eighty-six years. DR. EDWARD WIGGLESWORTH, of Boston, died on January 23d, aged fifty-six years. He graduated from the Harvard Medical School in 1865, and served during the Civil War. Dr. Wigglesworth was identified with dermatology, and founded a dispensary for skin diseases in 1872.

Anti-Cholera Serum.—A telegram from Berlin states that Dr. Behring has discovered an anti-cholera serum whose efficacy he is prepared to demonstrate.

Fire in the Matteawan Insane Hospital.—There was an outbreak of fire in the State Hospital for the Criminal Insane, on January 24th. The fire was started by one of the inmates, who had a mania for incendiarism. No serious damage was done.

Removal of St. Luke's.—The patients in the old building of St. Luke's Hospital on Fifth Avenue were transferred to the new hospital on Morningside Heights, on January 24th, and the old building was closed. The new building has only one wing which is completed, and about forty patients were moved into it.

Boycotted.—Our esteemed contemporary, the *Journal of the American Medical Association*, has a copious supply of news from numerous minor medical centres, but religiously excludes everything pertaining to the city of New York. The isolation is depressing. Is the journal preparing to move? If so we call its attention to a pleasant town situated on an island lying off the coast of Hoboken.

The Associated Health Authorities of Pennsylvania began their third annual session at Harrisburg on January 23d. In the discussion as to the duty of Boards of Health in the matter of diphtheria, the conclusion was reached that physicians should be called upon to report suspected as well as unequivocal cases of the disease and establish quarantine, or be subjected to a penalty. Dr. Robert L. Pittfield, Assistant Bacteriologist to the State Board of Health, dwelt upon the value of bacteriological examinations in cases of either established or suspected diphtheria. Dr. B. Meade Bolton, Chief of the Department of Pathology and Bacteriology of the Philadelphia Board of Health, presented a communication upon the "Advantages of Bacteriological Investigations to Boards of Health." "The Diphtheria Antitoxic Serum" was the subject of a paper by Dr. Joseph McFarland. Dr. J. T. Rothrock presented a paper upon "The Relation of Forests to Water Supplies" and Prof. Francis C. Phillips one on "The Protection of Water Supplies." At the closing session on January 24th the law for the restriction of contagious diseases was ex-

plained by Dr. Benjamin Lee, the Secretary of the State Board of Health. This law requires the placarding, flagging, or guarding in cities, boroughs, and townships throughout the State of all houses in which contagious disease exists. Dr. E. O. Shakespeare read a paper advocating the placing of the milk supply from its source to its distribution under the control of the sanitary board of health of the place where the milk is delivered.

Unlawful Knowing of a Female.—A bill has been introduced by Representative Broderick in the present Congress "to punish as a felony the carnal and unlawful knowing of any female under eighteen years." This is an amendment of the present law which fixes the age at sixteen.

Bellevue Hospital.—Dr. Charles E. Nammack has been appointed assisting visiting physician to the Fourth Division of Bellevue Hospital.

New York Academy of Medicine, Obstetric Section.—Dr. William Pryor was elected *Chairman* and Dr. S. Marx *Secretary* for the ensuing year.

Jefferson Medical College.—At the annual meeting of the Alumni Association of Jefferson Medical College on January 18th, Dr. A. K. Minich was elected *President* for the ensuing year. A proposition was made to collect \$10,000 from alumni of the school to aid in the equipment of the new pathological laboratory in contemplation.

For the Relief of Acting Assistant Surgeons.—Mr. Gallinger has introduced in the United States Senate a bill providing that all acting assistant surgeons whose names have been stricken from the rolls of the Pension Bureau shall be restored at once to the same, without the trouble and expense of filing a new claim; and all acting assistant surgeons shall be entitled to the benefits of all present and future pension acts the same as if they had been mustered in and out of the service of the United States. A similar bill has been introduced in the House by Mr. Baker, of New Hampshire.

The State Board of Medical Examiners of Virginia.—The General Assembly of Virginia is considering a bill providing for the appropriation of \$2,500 annually for the necessary expenses of the Board of Medical Examiners of that State. Their services were previously entirely voluntary.

The Deutsche Polyklinik.—A bill has been introduced into the New York legislature, giving \$15,000 annually to the Deutsche Polyklinik.

Dr. Eliza M. Mosher, of Brooklyn, has been made Professor of Hygiene in the University of Michigan, Ann Arbor, and Dean of the literary department.

Addison's Disease. On the evening of January 24th Dr. William Osler, of Johns Hopkins University, delivered an address before the students of the Medico-Chirurgical College on the treatment of Addison's disease.

Dr. Orville Horwitz has resigned from the chair of genito-urinary surgery in the Philadelphia Polyclinic.

The Cooper Medical College of San Francisco held its annual commencement on December 5th and graduated a class of seventy-six. Dr. Lane has promised the college the sum of \$2,000 to establish an annual course of ten lectures. This sum will be given for each course. The first series of lectures will be delivered by Dr. William Macewen, of Glasgow.

A New Health Bill for Virginia.—A bill has been introduced into the General Assembly of the State of Virginia to amend the laws relating to its State Board of Health. It provides that the governor shall appoint seven physicians, three from the city of Richmond and four from different sections of the State, who shall constitute the State Board of Health, the appointees to hold their office for four years or until their successors are appointed, vacancies which may occur to be filled by the governor. The board is to meet at the capital at least once in every three months; the salary of the secretary to be fixed by the board, and the other members of the board to receive no salary, but instead thereof to be paid four dollars a day while engaged in the performance of their duties and their travelling expenses incurred thereby; \$5,000 per annum is to be appropriated to defray the expenses of the board.

Trained Nurses did not Like a Basement Dining-Room.—The trained nurses of the Elizabeth, N. J., Hospital left in a body, because a separate dining-room was tendered to them in the basement of the institution.

We Sympathize with the members of the Woman's Medical Club of California, in the loss of one of its members, Dr. Euthanasia S. Meade. We trust her last moments were all that her first name implies.

Three Million Dollars Bequeathed to a Hospital.—The will of Mrs. Anna A. Aspinwall, a wealthy and somewhat eccentric Pittsburg woman, who died in Edinburgh, Scotland, last December, has been filed in Pittsburg. By the provisions of the will her entire estate, estimated to be worth \$3,000,000, is given to the Hospital of the Protestant Episcopal Church, Philadelphia. This hospital is maintained for the benefit of white female sick or convalescent orphan children. The will stipulates that there shall be no denominational discrimination, and asks that a preference be given to children who have lost both parents.

Manhattan State Hospital Bill Signed.—Governor Morton has signed the Manhattan State Hospital bill, which transfers New York City and County insane to State care, and brings the New York City asylums under control of the State Commission in Lunacy.

New York Pathological Society.—The second of the Middleton Goldsmith lectures will be delivered by Professor J. George Adami, of McGill University, Montreal, in the hall of the New York Academy of Medicine, on Monday, February 3d, at 8:30 P.M. Subject: "The Relationship between Inflammation and Certain Forms of Fibrous Hyperplasia."

Among the Beneficiaries of the recent Charity Ball was the University of Pennsylvania Students' Aid Fund.

A "University" for Selling Medical Degrees.—There is an institution in Chicago, known as the "Illinois Health University," which advertises in the daily papers. The business of this university seems to be to sell degrees of M.D., without personal examination, to persons living in those States which do not have any law regulating practice. The attention of the authorities has been called to it.

Paris has 6,000 medical students, while the provincial faculties of medicine in France have 4,000, thus making a grand total of 10,000 medical students. This is coming pretty close to the educational activity of America.

Celebration of the Centennial Anniversary of the discovery of the protective power of vaccine virus by Dr. Edward Jenner, 1796. The committee appointed by the American Medical Association and the auxiliary committee appointed by the American Public Health Association to prepare a proper programme for this centennial, propose the following order of proceedings, designed to occupy one entire day of the annual meeting of the American Medical Association, to be held in Atlanta, Ga., May 5 to 8, 1896: **THURSDAY, THIRD DAY OF THE MEETING—Morning Session.**—Address on "The Character of Dr. Edward Jenner and the History of his Discovery of the Value of Vaccination," by Dr. N. S. Davis, Chicago, followed by discussion on the history and status of vaccination in this country. **Afternoon Session.**—Paper on "The Scientific Researches Relating to the Specific Infectious Agent of Small-pox, and the Production of Artificial Immunity in this Disease," by Dr. George M. Sternberg, Surgeon-General, U.S.A. Also paper on "The Propagation, Preservation, and Use of Vaccine Virus," by Dr. Francis C. Martin, Boston, Mass. Discussion, especially on the scientific principles involved in the papers. **Evening Session.**—Paper on "The Statistic Evidences of the Value of Vaccination to the Human Race," by Dr. Eugene Foster, Augusta, Ga. Discussion as far as time will permit. **COMMITTEES.**—Of American Medical Association: Drs. N. S. Davis, Chicago, Ill.; J. M. Toner, Washington, D. C.; H. D. Didama, Syracuse, N. Y.; J. F. Hibberd, Richmond, Ind.; J. S. Billings, Philadelphia, Pa. Of American Public Health Association: Drs. T. George Simons, Charleston, S. C.; C. A. Lindsley, New Haven, Conn.; Angel Contreras, Pueblo, Mexico; J. M. Toner, Washington, D. C.; N. S. Davis, Chicago, Ill.

A Psychological Twist.—Dr. T. Lauder Brunton has made a psychological analysis of President Cleveland's message on the Venezuelan question, and concludes that it is really a powerful plea for peace.

Public Baths.—The Tenement-House Commission state in their report that only 306 persons out of a total of 255,033 inspected have access to bath rooms in the houses in which they live. At the "People's Bath," in Centre Market Place, the number bathing during December last was 4,683. Plans have been accepted by the city for new city baths recommended by the Committee of Seventy. When the recommendations

are fully carried out, there will be scattered through the city's crowded districts facilities for 25,000 daily baths.

The Five Most Useful Drugs.—In order to ascertain what drugs are most useful in general practice, the Willesden and District Medical Society requested every member to send in a list, and from this the following drugs have been selected: Iodide of potassium, antipyrin, liquor arsenicalis, tincture digitalis, and liquor strychnina.

Carlyle and Gray Powder.—Sir Richard Quain says that Carlyle was most eccentric as a patient. The only remedy he would ever take was a dose of gray powder. Says Sir Richard: "Gray powder was his drug when he had that wretched dyspepsia to which he was subject, and which was fully accounted for by the fact that he was particularly fond of very nasty gingerbread. Many times I have seen him sitting in the chimney corner smoking a clay pipe and eating his gingerbread. He overcame the difficulties incidental to this habit by his gray powder, which did him much good."

The International Congress at Moscow will open on August 19, 1897, and close August 26th. *President*, Professor Klein; *Vice-President*, Professor Kojevnikoff; *Treasurer*, Professor Filatoff; *Secretary-General*, Professor Frismann. There will be twelve sections.

We Feel Flattered.—If Colton is to be believed, imitation is the sincerest flattery. Therefore, rising above the good words and commendations upon the general appearance and general excellence of the *MEDICAL RECORD*, which come to our ear from every side, are the indications of appreciation which strike our editorial eye on looking over recent exchanges. We are pleased especially to note how well our short "hints" and "suggestions" are being taken here and there.

A Notable Judicial Decision.—The daily press announces a legal decision of interest to all physicians. Judge Stewart of Pennsylvania heard evidence in the claim of Dr. J. B. Schively against the estate of his aunt for medical attendance. Payment was refused upon several points, one of which was that the book presented by the doctor as evidence was not a book of original entry. The book was one of the standard physicians' visiting lists, in which calls are marked under dates by a dot, a cross, or a stroke, and then extended to the margin. Judge Stewart disallowed the claim, on the ground that the book was not one of original entries, but was merely a book of memoranda. As the great majority of physicians use such lists, the decision is one of moment to all members of the profession who make no other debit charges against patients. *The Journal of Medicine and Science* adds: "The substance of this item was given by Dr. Spalding in abstracts for October, and we took occasion to consult eminent legal authority in regard to its correctness. We were assured that all authority recognized that an account kept, as most physicians keep their accounts, with a mark or a dot to indicate charges,

is considered an original entry and an account kept in this way can be collected by law. When referred to this item, the answer was that there were circumstances warranting this decision or the judge didn't know the law. We intended to make this statement, and are now pleased to do so in this connection."

Acetylene Gas is a substance likely to prove useful in medicine and surgery. When lime and carbon mixed together are subjected to the heat of a properly constructed electric furnace, they are fused into a compound known as calcic carbon, which contains twenty parts of calcium and twenty-four of carbon. When water is added to this, decomposition takes place, with the result of forming calcic oxide, and a hydrocarbon compound which is known as "acetylene." This acetylene is a gas of an illuminating power from fifteen to twenty times stronger than that of ordinary gas. The light which it gives is white and brilliant, and has relatively fewer heat rays than ordinary gas. It seems that brilliant portable illuminators can be devised, and also that some cheap apparatus for thermo-caustic purposes can be produced. The portability of the gas, or of the substances which produce it, is another element greatly in its favor. The only serious objection to it, so far as we have learned, is that the gas is extremely poisonous—much more so than ordinary gas, and is of a lower specific gravity. In attempting to illuminate a house with it, therefore, perhaps some risk may be run, though probably this can be provided for eventually. It would not, in any event, apply to the limited use of the light for illumination in surgery.

Fees for Life Insurance Examinations.—The Marion County (Fla.) Medical Society has passed the following resolutions:

"WHEREAS, Some life insurance companies throughout the United States have reduced the fee for medical examination from \$5 to \$3:

"Resolved, That the members of the Marion County Medical Society refuse to make such examinations for less than \$5.

"Resolved, That this preamble and resolutions be spread upon the minutes of the society and published in the medical press of the United States."

Dr. Jameson is a Scotchman by birth, and was educated at University College, London. He became a Member of the Royal College of Surgeons in 1875, Bachelor of Medicine and Surgery of London University in the same year, and graduated as doctor in 1877. Shortly afterward he went out to Kimberley, where for many years he was the leading physician. He then formed the friendship of Mr. Cecil Rhodes, who came to him as a patient. He has been created a Companion of the Bath, and is the administrator for the British South Africa Company.

Doctors and Liquor Dealers.—The *Hospital* contrasts the change in the relative numbers of doctors and of saloon-keepers in England and Wales during the last quarter of a century, the former having increased at the expense of the latter. In 1871, the

number of doctors, in round figures, was 11,000 and of beer sellers, 14,000. In 1891, the number of doctors was 19,000 and the number of beer sellers 12,000. The *Hospital* draws a large number of interesting conclusions from these figures, which, however, seem to us to be entirely irrelevant. It is quite possible for saloons to centralize, as well as the general population, and it is within the bounds of every one's knowledge that one large saloon can sell more than three or four small ones.

Dr. Bevan Lewis, Medical Superintendent of West Riding Asylum, recently celebrated his silver wedding. He was presented with a number of valuable mementos by his friends and associates.

Hospital Superintendents and the Medical Staff.—The chief medical officer of the Cook County Lunatic Asylum has just been under trial before the county civil service board for insubordination to the lay head of the institution. It appears that without consulting his superior he made arrangements for a post-mortem of a patient whose death he could not otherwise certify.

Obituary.

KENNETH N. FENWICK, M.A., M.D.,
M.R.C.S. ENG.

KINGSTON, ONTARIO, CANADA.

DR. N. K. FENWICK, a well-known and highly esteemed member of the Canadian medical profession, died at Kingston, January 21st, at the age of forty-four. A gentleman of bright attainments, of sterling professional zeal, having a career brilliant with success, his death is a loss to the medical fraternity in Ontario, and especially to the community where he resided. Five days before his death, while operating on a child with septic peritonitis, Dr. Fenwick cut his finger, and although there was evidence of slight absorption it was only the day before his death that the case appeared serious. With terrific rapidity his forearm to the elbow became gangrenous, and the announcement of his death was to many the first intelligence of his illness. Dr. Fenwick was a native of Kingston, and for twenty years has been well known as a leading practitioner. After a brilliant collegiate course in Canada and England, he rapidly acquired a distinguished position in professional ranks. His untiring devotion to his patients, irrespective of personal comfort or health, distinguished him from the very commencement of his brilliant career. His special work in obstetrics and gynecology was early recognized and appreciated to such an extent that as a consultant he was highly esteemed. He was the author of a work on obstetrics designed for students, which has been received with considerable favor in Canada. His contributions to medical literature were always highly prized. Dr. Fenwick was a prominent member of the Canadian and Ontario Medical Associations, and held the chair in obstetrics in the medical department of Meen's University, Kingston. Reserved in manner, upright in action, and always ready to assist in every good work, this genial and scholarly Christian gentleman will long be remembered as a bright example of all those noble qualities which make up a most lovable man.

Reviews and Notices.

AN AMERICAN TEXT BOOK OF SURGERY FOR PRACTITIONERS AND STUDENTS. Edited by WILLIAM W. KEEN, M.D., LL.D., and J. WILLIAM WHITE, M.D., PH.D. Second Edition. Philadelphia: W. B. Saunders, 1895. 8vo, pp. 1,248.

THIS work, which is the joint production of a number of well-known surgeons, appears in its second edition somewhat increased in bulk. Numerous additions and elaborations have been made with a view of keeping the discussion of the multiple topics up to the requirements of recent advances in the surgical art. The announcements in the preface are, however, hardly up to the fulfilment of some of the promises; for instance, acromegaly, instead of occupying a so-called section, comprises but two or three paragraphs embodying the statements that the bone complications are really due to increased proliferation of osseous tissue and that the disease is beyond surgical skill. As to brevity of other additions very much the same may be said, but in the main they cover essential points. These are, however, minor matters, bearing in mind the necessity of keeping the bulk of the volume within reasonable limits. The Hartley-Krause method of removing the Gasserian ganglion is well and intelligently described and the illustrations serve their purposes. The osteo-plastic method of resection of the skull is also given, with some useful hints of technique. Schede's osteo-plastic operation on the chest wall is well illustrated, as is also Witzel's method for gastrostomy. The use of Murphy's button is compressed within limited range, and the description of the operation is correspondingly condensed. Macewen's method of compressing the aorta for amputation at the hip-joint receives its limited description in just comparison with other more effectual and safer ones. Symphyseotomy is described with necessary precision and detail. Although the radical extirpation of the breast, which includes the removal of one or both pectoral muscles, is well described, it would be still more intelligible if a suitable illustration of the various steps had been inserted. Many of the illustrations throughout the work are new and the names of instruments have been omitted from several of the cuts, thus improving their appearance.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS IN PHOTO-LITHOCHROMES FROM MODELS IN THE MUSEUM OF THE SAINT LOUIS HOSPITAL, PARIS. With explanatory woodcuts and text. By ERNEST BESNIER, A. FOURNIER, TENNESON, HALLOPEAU, DU CASTEL, HENRI FEULARD, and LÉON JACQUET. Edited and annotated by J. J. PRINGLE, M.B., F.R.C.P., Assistant Physician to, and Physician to, the Department for Diseases of the Skin at the Middlesex Hospital, London. London: F. J. Rebman, Publisher, 11 Adam Street, Strand. Philadelphia, U.S.A.: W. B. Saunders, Publisher, 925 Walnut Street, 1895.

It has been justly said that the wax models of the St. Louis Museum, under the skilful touch of Monsieur Baretta have reached a perfection which challenges the admiration of the entire medical world.

It is now for the first time that, in point of fact, the whole world may, if it choose, see these models; not in their reality, but so artistically reproduced as to make a visit to the Paris collection unnecessary. In the plates of Part I, which has reached us, one gets the idea of elevation of the lesions above the surface which it is so difficult for an artist to bring out when drawing from life, and as so often happens, under a time pressure. The coloring might be termed pathological perfection.

There are some eighteen hundred models in the museum which will remain, as it were, a monument to the achievement of the renowned Baretta. That a suitable selection from these is to be published will be no less a source of satisfaction to those who have already done so and who expect again to visit and study the originals, than it should be gratifying to all those who have this as their only opportunity to enjoy and profit by the celebrated collection.

An interesting feature of the Atlas is the descriptive text, which is written for each picture by the physician who treated the case or at whose instigation the models have been made. We predict for this truly beautiful work a large circulation in all parts of the medical world where the names *St. Louis* and *Baretta* have preceded it.

ATLAS OF THE DISEASES OF THE SKIN. By H. RADCLIFFE CROCKER, M.D., F.R.C.P.; Physician to the Department for Diseases of the Skin, University College Hospital; formerly Physician to the East London Hospital for Children; Examiner in Medicine at Apothecaries' Hall, London. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co.

THIS work is approaching its completion. Fasciculus XIII. is before us. We regret that only three more are to follow. Each one has been a source of renewed pleasure. Not all the drawings are of equal excellence, but the average is high. The present number contains upon its six plates no less than nineteen figures.

The Erythema nodosum strikes us as being too bright in color, but the E. iris gives an excellent idea of the affection. "Psoriasis" is not typical enough to stand alone, but as there has appeared in former numbers a variety of other different forms, this group of three excellent figures serves a useful purpose.

Phases of pityriasis rubra pilaris and a fairly good representation of lichen planus are shown in the text plate.

Molluscum contagiosum, with large suppurating lesions, is well illustrated on a plate, along with two figures of vascular nevus.

Fig. 3 of Plate LXVI. is given in the contents as "Psoriasis on breast" while it is clearly a psoriasis form variety of lupus erythematosus, as indicated on the plate.

The title of the last plate, as well as the heading of the text, is misleading. "Tinea Cruris et Larva Migrans; Synonym: Eczema Marginatum," would appear to apply to the prominent figure of the plate, whereas the larva disease is illustrated by the smaller figures alone.

DIE LEHRE VON DEN NASENEITERUNGEN. Von DR. LUDWIG GRÜNWALD in München. Zweite gänzlich umgearbeitete Auflage. Mit 8 Abbildungen im Text, 2 Tafeln und einer Tabelle. 1896. München: Verlag von J. F. Lehmann.

THE first edition of this monograph was conceded on all sides to be the best presentation extant of the general subject of disease of the accessory nasal sinuses. The present edition is essentially an amplification of the first, following the latter in its general arrangement. A larger number of clinical cases was at the author's disposal in its preparation, and he has consequently been able to reinforce his conclusions from this additional experience. The praise bestowed upon the first edition is amply deserved by the second.

STATISTICHE E CONSIDERAZIONI CLINICHE DI OTORRINO-LARINGOIATRIA. Su 4393 ammalati curati nell'anno 1894. Pei Dottori V. NICOLAI e T. DELLA-VE-DOVA. Milano: Tipografia del Riformatorio Patronato. 1895.

THIS is merely an annual report of the nose and throat service in an institution with which the editors are connected. They appear to have followed modern methods in their labors, and to have worked up their clinical cases with commendable thoroughness.

INJURIES AND DISEASES OF THE GENITAL AND URINARY ORGANS. By HENRY MORRIS, M.A., M.B. Lond., F.R.C.S.; Surgeon to, and Lecturer on Surgery at, the Middlesex Hospital; Member of the Council and of the Court of Examiners of the Royal College of Surgeons, England; Examiner in Surgery in the University of London. With ninety-seven illustrations. New York: William Wood & Company. 1895.

THE author regards this volume as, in a way, a continuation of his book on the "Surgical Diseases of the Kidneys," and has followed the general plan adopted for that work as more suitable to the wants of the practitioner and student than the arrangement by clinical lectures.

The details of technique will not be found so fully discussed as the principles upon which operative procedure is based. While generally accepted plans of treatment are given and described, the author's own convictions, based upon long experience, are always made prominent. While many of the illustrations have been especially prepared for this work, others may be recognized as having served in the "Manual of Surgery," edited by Mr. Treves, but all, not otherwise credited, were originally made under the author's direction from the Middlesex Museum collection.

There are fourteen chapters on diseases of the genital

organs, twenty-one on the genito-urinary, and twelve on those of the urinary bladder. These make up a very practical manual, from which we can gain an excellent idea of our present knowledge of these subjects.

It is not intended for the expert operator in genito-urinary surgery, but rather as a guide to him who would become such, or to the student who must prepare himself upon this branch of medicine. The specialist must, however, read the author's views upon many of the topics with interest, especially those pertaining to stricture and its cure, diseases of the prostate, etc.

One advantage of this work over some that have recently been produced is that it can be held in the hands, and the reader is not forced by the *avouirdupois* to absorb his knowledge bent over a table.

A MANUAL OF SYPHILIS AND THE VENEREAL DISEASES.

By JAMES NEVINS HYDE, A.M., M.D., Professor of Skin and Venereal Diseases, Rush Medical College; Dermatologist to the Presbyterian, Michael Reese, and Augustana Hospitals; and Consulting Physician to the Hospital for Women and Children, Chicago; and FRANK H. MONTGOMERY, M.D., Lecturer on Dermatology and Genito-Urinary Diseases, and Chief Assistant to the Clinic for Skin and Venereal Diseases, Rush Medical College; Attending Physician for Skin and Venereal Diseases, St. Elizabeth Hospital, Chicago. With forty-four illustrations in the text and eight full plates in colors and tints. Philadelphia: W. B. Saunders, 925 Walnut street. 1895.

THE collaboration of these authors has resulted in an attractive manual which covers the ground while not exhausting it. The introduction begins on page 17 (just why it should not be page 1 or page 9 is not clear), syphilis is considered in the following 267 pages, and the remaining 313 pages, exclusive of index, are taken up with the various venereal disorders, including stricture and its treatment. Five of the eight plates are colored, two showing tongue lesions after Hutchinson.

The frontispiece would most likely startle the non-professional seeker after knowledge who might casually open the volume. It shows an "initial sclerosis of the penis"—with less sclerosis than penis.

One always expects a slight shock from some part of a volume on this subject, but it doesn't always come upon one with such premature suddenness.

It is not because of a lack of venereal works that the present was undertaken (the authors acknowledge their indebtedness to many recent ones), but the manual is designed to meet the wants of the student and busy practitioner, and it does it in a worthy manner.

We would suggest that in a future edition (may there be many) something may indicate whether the red or the blue, or both, are the strepto-bacilli of Ducrey in plate 7, or why some are colored blue and others red.

On page 291, it seems to us, a faulty use is made of the term "male prostitute." So far as we remember, this term was first employed, in recent times, to designate the genital pervert who offers himself to infamous practices for hire, and it has since been used by writers in this sense. To make it apply to all men who have occasional intercourse with prostitutes is not consistent with the etymology of the word.

A VOICE IN THE WILDERNESS. By MARIA A. L. D.

Chicago: Laird & Lee. 18mo, pp. 224.

THIS little book is the story by a woman of a woman who had been taken captive by morphine. It is another "tale of the poppy," and it points a moral that well adorns.

It has the merit of freedom from that hyperbole which so often pertains to authors of this class, and of being exceptionally correct—from the standpoint of a medical writer—as regards the cause and ethics of a disease (not a habit) that has brought more of sorrow than the world will ever know.

Helen Mathews, whose wail is the "Voice in the Wilderness," was the victim of a railway accident, and to relieve the agony from which she suffered the drug was given, and history repeated itself.

The outcome was not at all surprising: it is the almost inevitable sequel of such a situation. The author says, "the bravest have succumbed to its influence;" and she is right. The man or woman does not live, who, under certain conditions, can stand up against the power of morphine.

The added sorrow of the hapless sufferer who realizes her

prostrate will—direct result of the direful drug, her impotent resolve, and that "cruelty of ignorance" which makes those who are otherwise friends look askance on so-called "moral lepers" such as she, is well depicted. So, too, is emphasized the wise counsel that placed her under special care.

PRINCIPLES OF SURGERY. By N. SENN, M.D., Ph.D., LL.D., Professor of Practice of Surgery and Clinical Surgery in Rush Medical College, Chicago. Second Edition. Royal octavo, pp. 656. Cloth. The F. A. Davis Company, Philadelphia.

THE second edition of this work appears with a revision of its entire contents and with several important additions, principally in the direction of elaborating the more essential principles of surgery relating to the etiology and pathology of surgical diseases.

Aside from references to the more recent advances in surgical pathology, there is added a description of the technique of the more important operations, together with the application of general principles to special pathological conditions. It is in this latter respect that the work as it was and as, in its improved condition, it now is, gives ample evidence of the painstaking character of the author's efforts in keeping it fully abreast of the advanced thought of the day. The minute and intelligible description of pathological processes, and their direct relations to bacteriological influences, make an especially distinguishing feature of the treatise which cannot fail to impress every advanced student and every progressive practitioner.

MANUAL OF GYNECOLOGY. By HENRY T. BYFORD, M.D., Professor of Gynecology and Clinical Gynecology in the College of Physicians and Surgeons of Chicago. Philadelphia: P. Blakiston, Son & Co. 1895.

THE work before us is safe, practical, and concise. It is intended mainly for advanced students, and does not go into great detail, especially in matters of a controversial nature. Within this scope aimed at by the author, modern gynecology has once more received adequate treatment at the hands of an author competent to give it.

NOTES ON SURGERY FOR NURSES. By JOS. BELL, M.D., F.R.C.S., Edinburgh. Fourth Edition, Revised. Oliver & Boyd, Edinburgh. 1895.

THIS brochure of 175 pages is the outcome of conversational lectures to the nursing staff of the Edinburgh Royal Infirmary. It is attractively written, and is abounding in hints to the conscientious nurse. Much of the matter is such as of old was the property of the assistant of the surgeon and appealed directly to the visual sense.

In the work, cleanliness, accurate observation, and truthfulness are insisted upon; diagnosis and pathognomonic symptomatology also receive their share of attention. The concluding chapter on "General Advice to Nurses," ethical in tone, abounds not a little in worldly wisdom. The treatise, on the whole, is a handy *vade mecum* to be consulted off and on in moments of leisure with pleasure and profit.

CATARRHAL DISEASES OF THE RESPIRATORY PASSAGES.

By J. M. G. CARTER, M.A., M.D., Sc.D., Ph.D. E. H. Colgrove & Co. 1895.

THE author, who some years ago was reporter at Waukegan for the Illinois Weather Signal Service, began a study of facts brought immediately under his notice, and gradually availed himself of accredited statistics from numerous sources.

The field is a wide one, and is well covered by an intelligent appreciation of the wider aims of etiology.

LABORATORY MANUAL OF INORGANIC PREPARATIONS.

By H. T. VULTÉ, Ph.D., and GEORGE M. S. NEUSTADT. New York: Geo. Gottsberger, 11 Murray Street. 1895.

THE book introduces the student into practical work in the field of inorganic chemistry. It gives explicit descriptions of synthetic work, and shows how compounds, often very complex in character, rare in occurrence, or expensive in preparation, may be produced from simple substances, or from those which are comparatively plentiful and cheap. The book is designed to train the student to prepare his own reagents and to test them for the customary impurities.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN GENERAL MEDICINE.

Regular Meeting, Tuesday Evening, January 21, 1896.

DR. W. H. PORTER, CHAIRMAN.

Theory and Treatment of Rheumatism.—DR. LOUIS FAUGÈRES BISHOP read the paper on this subject (see page 150.)

The Clinical Aspects of Rheumatism.—In opening the discussion, DR. WILLIAM H. DRAPER said it was hardly necessary to remark that each one could affirm from his experience that it was hard to find a more difficult subject to present than that of rheumatism. It was well to remember that the name rheumatism was applied to an articular lesion. It had seemed proper to him to classify the lesions under three heads: first, the neuropathic; second, humoral; third, bacteriological. He had seen all the neuropathic forms in rheumatoid arthritis, etc., and he thought there could be no doubt as to the applicability of the term to these lesions. The second, humoral, embraced many cases in all probability due to imperfect metabolism of food. The bacteriological forms could be recognized without difficulty from their similarity to some of the essential fevers. Dr. Draper said one striking fact, which led to the conclusion that acute rheumatism was bacteriological, was its epidemicity. While rheumatism was not often seen as an epidemic, he thought there was no doubt that it sometimes presented some of the symptoms. Articular rheumatism was affected by seasons and was seen more frequently some years than others. These variations of time of year, etc., could only be explained by supposing it a disease of bacteriological origin. There was no reason why a neuropathic rheumatism should appear more in one year than in another, or more at one time of year than at another, nor would those due to blood change be likely to occur more at one time than at another. It was known that typhoid and many other diseases were more frequent after long, dry spells followed by rain, and it had been shown by some that it was the same with rheumatism.

From the clinical side, acute articular rheumatism was much like the infective diseases. The onset was similar, and the course was often irregular, with recurrences which are not so common since the use of the salicylates. He thought the occurrence of hyperpyrexia was more likely to accompany an infectious disease than an ordinary inflammation of a joint. The blood changes were analogous to those of other infective fevers. Then, rheumatism, like other infectious diseases, was not always confined to articular surfaces, but was found in connection with visceral lesions, such as endocarditis, which shows there was a cause that was general and constitutional. He had often been struck with the resulting anæmia and thought there was no disease perhaps in which the resulting destruction of the corpuscular elements was so extensive. This seemed to indicate some general cause, as in the other infectious diseases.

There were deductions to be drawn from the treatment. The lactic acid seemed to be more a result than a cause, and the alkaline treatment based upon it as the cause of the disease had been abandoned long since, yet alkalies were serviceable with the salicylates, but ineffectual in curing the disease. He thought the success of the salicylic-acid treatment confirmed the idea that the disease was due to a specific cause, for it was known from experience that its administration was nearly as effective in relieving the

pain and the fever as quinine in malaria, or the iodide of potassium in syphilis.

The so-called hybrid cases seemed sometimes almost to force us to conclude there were two poisons in the system to produce the conditions. We often met cases which seemed to be cases of generalized gout, and we have seen symptoms that made us think there was a rheumatic element. He suspected these were cases of rheumatism of a mild degree, as both mild and severe forms were seen in many diseases, as in the grippe. It was not unlikely the germinal powers of rheumatism could produce slight effects, and slight attacks might occur as well as severe ones. He did not believe gout was incompatible with rheumatism, and a gouty person might be rheumatic.

In all the infectious diseases we had to consider the resistance in the individual to the disease-producing cause, and this consideration might help to explain many cases of rheumatism, especially in the deformed joints of the old.

DR. ROBERT W. TAYLOR said he had for years looked upon lactic acid as one of the results in rheumatism. Twenty-five years before, he had demonstrated to a class lactic acid in the blood from a rheumatic patient, but then thought it might be the ashes of the disease instead of the cause. Dr. Taylor said that by contrasting rheumatism and gonorrhœal rheumatism some deductions might be drawn. The gonorrhœal rheumatism was known to be an infectious disease. The gonorrhœal form did not jump from one joint to the other, the fever was less but always present, in both there might be heart affection, the general effects were the same on the system, in both there might be purpuric spots, and in both eye affections sometimes occurred. There was a distinct parallelism between the two. He had seen six cases at least in which the symptoms complicated syphilis. In these three diseases there was but one in which there was known to be a micro-organism, yet it was generally agreed that syphilis was due to a micro-organism, and it would be reasonable to conclude that rheumatism was also. It was said the intestines were the seat of many microbes which were saprophytic but not injurious. Some of these had active influence in the process of digestion. Is it not possible that some of these take on a pathogenic form and secrete a poison? Acute rheumatism often looked like a series of poisonings; thus, one day a joint was seriously affected and the next it was well, but another was affected. He offered this only as a suggestion, as he could think of no other seat of the disease than the intestines. The word rheumatism was used for many conditions and some of these he thought were due to a deep-seated urethritis.

DR. BEVERLY ROBINSON said he would ask the gentlemen to listen to his remarks as simply arising from experience. He was most interested in Dr. Draper's remarks on so-called hybrid forms of rheumatism. His clinical experience did not always correspond to what the books said. He often found cases in which the urine was that of rheumatism, but in the condition of the patient there was more of the gouty than rheumatic state. He had patients who never yielded to any form of treatment except colchicum, and yet bore the appearance of rheumatism. These were not affected by the salicylates, change of climate, or diet, but colchicum gave relief. He often found the urine left one in doubt as to whether he should expect gout or rheumatism.

Dr. Robinson said he thought all agreed that the lactic-acid theory was not sufficient, but lactic acid was an attendant upon the condition and not the cause. He did not think it was best to give large amounts of the salicylates, for they had a depressing effect upon the patient, and he did not get as good re-

sults as he did from smaller doses. It was well also to combine a little colchicum with the salicylates. He had used chloride of ammonium and acetate of potash, ten to fifteen grains each every two hours, with good results. In the treatment of the subacute forms of rheumatism he thought it was often best to resort to surgical means and immobilize the joint, even with plaster-of-Paris; especially was this true of the knee and ankle joints. Massage helped at times, but often he had been sadly disappointed in the results. The sending of patients to watering-places often did good, and one of the best places in the United States during the summer time was the hot springs of Virginia.

DR. W. H. THOMSON said that while Dr. Bishop was reading his paper he thought of the condition of the profession previous to 1880, regarding the cause of tuberculosis; how, if it had not been for the bacteriological advancements since that time, doubtless the profession would now be discussing the etiology from symptomatology and pathological lesions without approaching the real cause. He thought the same might be applied to the discussion of rheumatism. He thought such would be the condition in regard to rheumatism until experimental medicine came to their aid. He was not sure whether it would demonstrate it as due to a micro-organism or to a leucomaine, as gout was. Reasoning by exclusion lent some aid. In the first place rheumatism was not gout. Acute rheumatism was a disease of childhood and early adult life; moreover, in early life the poison was particularly dangerous, more so, as a rule, than in adult life because of the slight joint affection, which might also endanger the heart. It might also act on the nervous system, as well producing chorea. The liability to a first attack of rheumatism decreased after the age of thirty, and after forty it did not occur as a primary attack. Gout was delayed generally until the individual was thirty before it developed as a true attack of gout. Gout was mono-arthritis on its first visit, and might not leave the joint attacked for several years. Not until it had attacked the knees did it become generally distributed through the joints. Rheumatism was generally polyarthritic from the beginning, and more likely to be so in the first attack than in the others. Dr. Thomson said he could differentiate between rheumatism and gout by the pulse. In gout the pulse was incompressible, the artery full, showing some disturbance in the arterioles due to an insoluble poison in the blood. In rheumatism the pulse was distinctly compressible, showing that the poison in the blood was soluble.

There was a difference in their anatomical lesion. Rheumatism attacked the heart and serous membranes, especially the pleura, primarily, but when gout attacked the heart it was secondary to arterial disease when the heart was already worn out.

Gout caused gouty bronchitis, so for a long time it had been the custom to give colchicum for bronchitis. On the other hand rheumatism generally avoided mucous membranes. In gout there were likely to be kidney lesion and deposits in the cartilage of the ears.

The two were certainly not related clinically or pathologically. When gout visited a joint it left its card there, but in rheumatism, if any other condition caused such apparent trouble in a joint, we would think it time for the surgeon to interfere, but the next day there might be no sign, and an autopsy would reveal no lesion. The points of tenderness were not the same in gout as in rheumatism.

Dr. Thomson said he lived at one time in a country where there was no gout except among a few English, or priests who used wine. The people being Mohammedans, they were not allowed to drink wine. In America previous to the introduction of lager beer gout was an aristocratic disease, but lager beer had

done away with this aristocracy, and now it was as much an American disease as an English one. In Scotland more whiskey was drunk than in any other country, but the Scotch were not gouty, while in England, where much beer was drunk, gout prevailed. Gout followed closely the use of fermented liquors.

In considering the etiology of rheumatism, it should be remembered that it prevailed wherever people were likely to be chilled while wet. When the skin was not chilled when the person was wet, rheumatism was not likely to occur. There were two countries where rheumatism prevailed endemically, in Scotland, where there was much dampness and wind, and in Arabia, where the atmosphere was intensely hot and dry. The reason it prevailed in Arabia was that the heat was intense during the day, but the radiation at night made it very cold about two or three o'clock in the morning. Persons going to bed perspiring from heat were thus chilled while wet. He thought Arabia justified the opinion that the skin had as much to do with the cause of the disease as anything else. Might it not be that the skin maintained a necessary balance between the atmosphere without and the blood within, and a disturbance of this relation produced the untoward results? Why was it there was local rheumatism? He had seen cases of local rheumatism brought on by exposure to cold of the part alone.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninetieth Annual Meeting, held at Albany, January 28, 29, and 30, 1896.

ROSWELL PARK, M.D., OF BUFFALO, PRESIDENT.

TUESDAY, JANUARY 28TH.—*Morning Session.*

President's Inaugural Address.—The ninetieth annual meeting opened with unusually bright prospects. Recently there had been organized a world's congress of climatology and the secretaries of State medical societies had been requested to appoint delegates, and this had been done for New York by Dr. Curtis. The first meeting is to be held at San Antonio, Texas.

The profession was to be congratulated on the continuance of the *Index Medicus*.

The growing importance of the medical department of the State Medical Library deserved attention. With some difficulty an appropriation of five thousand dollars was secured from the legislature last year, and this amount ought to be appropriated every year.

Representation from incorporated medical societies was now liable to abuse.

The president urged upon the members the importance of hastening by all judicious means restoration of former relations between this society and the American Medical Association. Opposition to this was now continued by only a few individuals. A change of meeting-place was recommended, there being many reasons for selecting the metropolis in preference to the capital. Dr. Park also thought meetings should be held at times in the western part of the State. There should be a radical change in the new law relating to instruction on alcohol and tobacco in the schools of the State. Another subject for legislation was the coroner system. The profession should have the protection of the law against unjust suits, for nearly all malpractice suits were unjust.

There was a growing tendency on the part of the State Commission in Lunacy to assume all responsibility and secure centralization of all power of management of institutions in the State. The personnel of the commission was liable to be changed at any time, and as no one knew of whom it might be composed it became

evident that great abuses might creep in. If it obtained the power sought it would have the direction of the expenditure of four or five million dollars a year.

On motion of DR. LUCIEN HOWE, the recommendations contained in the address were referred to a committee of five. The president appointed the committee, with Dr. Howe as chairman.

Reports.—The secretary, DR. F. C. CURTIS, in his report read a list of newly-made permanent members. DR. PORTER, treasurer, stated that there was a balance in the treasury of over twenty-two hundred dollars.

By-Laws.—The committee on by-laws recommended only one delegate from incorporated societies, the membership of which should be at least fifteen. Adopted. Some other unimportant recommendations were made.

No complaint had been presented during the year for consideration by the committee on ethics.

Prize Essay.—DR. A. JACOBI read the report of the committee. One essay of value had been received, from which extracts were read. It was on diseases of the stomach. The prize was awarded to this author, whose name proved to be Dr. A. L. Benedict, of Buffalo, N. Y.

Duties of Nurses in Cases of Ophthalmia Neonatorum.—DR. LUCIEN HOWE read the report of the committee on this subject. The committee had called the attention of midwives and others to the existence of the present law for the prevention of blindness. It was recommended that the law of 1891 be made more definite. The matter was referred to the committee on legislation.

To Regulate Midwifery.—DR. M. D. MANN brought up the question of county examinations of midwives, and a special committee was appointed to draft a bill similar to that which had applied to Erie county since 1885.

A Local Remedy for Psoriasis.—DR. L. D. BULKLEY, in a paper of five minutes' duration, called attention to permanganate of potassium, one to two per cent. solution, as a means for relieving local pruritus. A patient had called his attention to its value two years ago. Of course it was not intended to replace dietetic and hygienic measures.

Water and Its Relation to Disease.—DR. W. P. MASON, of Troy, read the paper. Mechanical reduction of turbidity, as by silk, was of some efficiency. The influence of minerals in water was of interest, but by far the most important cause of disease was bacteria. A cholera outbreak at Messina, Italy, witnessed by the author, was suddenly checked when contamination of the water supply by washing clothes in it was stopped. A fellow-student in Pasteur Institute experimenting with cholera germs took the disease from a cigar. The increase of typhoid fever after floods was not due, as stated by Pettenkofer, to rise of water in wells, but rather to its prior lowness. From a pecuniary point of view it was much cheaper to a community to furnish a healthy public water supply than to lose so many able-bodied citizens by a preventable disease.

DR. L. S. PILCHER, of the committee on hygiene, discussed the paper, and opposed a bill before the legislature prohibiting the cutting and sale of ice on all rivers throughout the State. While the ice from certain localities on rivers might be impure, such sweeping legislation would be very unjust and injurious.

DR. A. JACOBI called attention to the tendency of running water to purify itself, particularly when forming ice, by settling of impurities, etc.

DR. G. V. R. MERRILL said that in Chemung County there had been remarkable freedom from typhoid during a dry spell, with an outbreak after rains. Three bacteriological examinations reported typhoid germs in the river water. Now ice was being cut; was this safe?

DRS. BAKER and SHIPP opposed legislation excluding sale of all ice from rivers.

DR. H. S. DRAYTON from examination knew of the impurity of Passaic River water, yet during the past summer, while it was low, typhoid fever had been unusually scarce in Jersey City, which got its water from the Passaic. He mentioned it as a hygienic vagary.

After some further discussion the resolution of the committee on hygiene was declared out of order.

Sepsis of the New-Born.—DR. M. A. CROCKETT, of Buffalo, in this paper mentioned as sources of infection in the new-born the umbilicus, lungs, etc. The umbilicus was the chief source of infection. The symptoms were often obscure, but various. Rise of temperature was an important one.

DR. A. JACOBI mentioned as roads of infection the umbilicus (the chief one), the skin, especially when roughly rubbed with impure soap, the lungs, the mucous membrane of the mouth, which was very tender and often injured by cleansing with the nurse's (dirty) hands; swallowing germs; infection through the anus.

Rise of temperature was often observed in the new-born without other symptoms.

The Question of Puerperal Self-Infection.—DR. CHARLES JEWETT in this paper gave the results of his own observations and of those of others in private practice, and of hospital practice in Brooklyn and New York, regarding vaginal and non-vaginal irrigation before and after labor. The conclusion arrived at from these observations, and more especially from the parallel experiments in the two ways by Leopold and others, was that the vaginal douche in healthy women before labor was contraindicated and added slightly to the mortality. If there were vaginal pus before labor, the canal should be cleansed. Strict external antiseptics and asepsis were highly important.

A Medico-Legal Note.—DR. A. WALTER SUTER in this paper referred to a medico-legal case, in which he had expressed the opinion in court that a bullet exposed to light heat while passing through air, etc., is aseptic. He now admitted this opinion was a mistake, as had been shown by experiment. Bullets were not necessarily aseptic.

FIRST DAY—Afternoon Session.—The report of the committee on hygiene in opposition to the bill condemning sale of all ice cut from rivers was adopted.

Report of the Committee on Legislation.—DR. MORRIS J. LEWIS read the report. One portion of it, he said, was a compromise. It recommended that students entering medical colleges be allowed one year in which to fulfil their academic requirements for admission.

DR. A. JACOBI opposed this part of the report and on motion it was stricken from the report.

Shall the State Attempt to Control Spread of Tuberculous Disease?—DR. J. L. HEFFRON, of Syracuse, read the paper. His conclusions were: 1. Tuberculosis is an infectious, preventable, and curable disease. 2. The State should attempt regulation. 3. A circular of facts relating to these points should be sent to patients. 4. Instruction should be given in schools, etc. 5. Owners of halls and conveyances should be compelled to take measures to prevent infection, and to use disinfection where contamination had occurred. 6. The hopelessly sick, and the vicious who would not obey rules of prevention, should be isolated.

DR. A. JACOBI coincided with the conclusions of the author. The fear of centralization was less strong in this country than formerly. It was but a step from State control of diphtheria and scarlet fever to like control of tuberculosis. It was now applied to barracks and prisons, why not to schools? In Italy and some other European countries insurance companies found it to their advantage to pay expenses in sanatoria

of the insured suffering from tuberculosis. Would it not repay the State to do the same?

DR. E. J. BRUSH, of Mt. Vernon, thought it was confusing to physicians and the laity to connect tuberculosis with diphtheria, scarlet fever, and other acute infectious diseases. The latter had a definite and short period of incubation. One might be infected with tuberculosis and not develop symptoms for years. He had once read a paper showing that the only countries free from tuberculosis were those where the cow was not domesticated. Further, he had shown that the normal temperature of the cow was 102° F.

It was only when the human subject attained a temperature of this grade that the development of tuberculosis was favored, provided infection had taken place. It was a mistake to place too much stress on sputa in halls, etc.

Discussion on Early and Latent Syphilis in Infants and Young Children.—DR. GEORGE T. ELLIOTT, of New York, opened the discussion. Hereditary syphilis might show symptoms at birth, or not until after three or more weeks, or much later. Syphilitic stigmata at birth were general marasmus, look of old age, snuffles, coryza, and lesions of syphilis. Lesions developing in healthy-looking infants a few weeks after birth were apt also soon to be followed by the general signs of marasmus. It was not possible to divide cases, as in the adult, clearly into secondary and tertiary. The individual symptoms in the nature of bullæ, condylomata, mucous patches, etc., were considered, more especially in differentiating from certain skin affections, as psoriasis or urticaria. Syphilis of bones was apt to show rounded enlargement of the ends, perhaps separation of the epiphysis, and ulceration with skin lesions. After the development of the second teeth the Hutchinson teeth, notching of the middle incisors, pointed to syphilis.

Nervous Manifestations.—DR. B. SACHS, of New York, read a paper on the nervous manifestations of syphilis in children. The evidence pointed plainly to the fact that cerebro-spinal syphilis was an extensive disease with light intensity. In two hundred cases of infantile palsy syphilis was the cause in but one. Syphilis was an infrequent cause of idiocy. The lesions were of the pia and vessels, gumma of brain or cord, myelitis following lepto-meningitis.

DR. L. D. BULKLEY read some notes. While syphilis was on the increase in this country, he saw less of hereditary syphilis in infants, and attributed the decrease to early recognition of the disease and treatment by family physicians, and to prevention of conception by those having syphilis. Treatment should be persisted in, as in the adult, after disappearance of symptoms. This consisted of the use of mercurial ointment, diluted one-half, under the bandage, and iodides, especially iodide of iron in syrup.

DR. MAER, of New York, related a case of difficulties in diagnosis, except for physical evidence (nasal), of syphilis in three generations.

DR. E. D. FISHER agreed with Dr. Sachs that it was difficult to say a given case of cerebral hemiplegia was syphilitic or due to hemorrhage. It could be explained by compression or meningeal hemorrhage.

The Equilibrium Function of the Ear.—DR. GAYLORD P. CLARK, of Syracuse, in this paper showed specimens and discussed the equilibrium function of the ear, based on experiments on the dog-fish, etc., and reports of cases of disease in man. The evidence was that the ear was a compound organ, with two circular canals on each side; that they functionated in pairs, and their primary purpose was to maintain the equilibrium of the body in turning, etc. Disease in man went to show a similar function, and that audition originally was only secondary. Otolithic structure of the ear likewise confirmed this view.

Discussion: Diseases of Intra-Uterine Life.—DR. EGBERT H. GRANDIN opened the discussion with a paper on the transmission of disease to the fœtus through the mother. The subject was involved in much obscurity. There was little evidence of a positive nature, yet experiment and observation had shown that the various infectious diseases could be and had been transmitted from mother to fœtus in utero. Among those mentioned were variola, scarlet fever, and erysipelas. He had found but one case recorded of transmission of tuberculosis, and few cases of septicæmia. The facts regarding syphilis were well known. Only one disease of this class had not been transmitted as far as known—anthrax.

The second part of the paper considered theories as to how transmission occurred. The two principal theories were, transmission through blood-vessels, transmission through lymph channels. The theory which seemed to the author the more likely was that of transfusion or migration of leucocytes through the placenta, which stood between the circulation of the mother and that of the child.

Eclampsia and Uræmia.—DR. P. W. VAN PEYMA, of Buffalo, in a paper on this subject arrived at the generally accepted conclusion that the active agent in eclampsia and uræmia was a toxic agent. By uræmia was no longer meant poisoning by urea. Regarding the nature of the toxic agent, the urine in jaundice was especially toxic, in eclampsia less toxic than normal, while the blood serum was more so. The bile was six times more toxic than the urine in jaundice. Methods of treatment had been based on the toxic theory. But the amount of toxic principles removed by increasing urinary secretion, catharsis, and sweating was limited. More was removed by abstracting blood, but venesection had not given results hoped for. There was some recent experience favoring diluting the poisonous blood by saline injections, and these favored removal by diuresis and diaphoresis. The author also discussed the value of medicinal agents—veratrum, morphine, etc. Pilocarpine was condemned, as well as over-medication by chloroform, etc.

Medical Education of the Future.—CHARLES W. ELIOT, president of Harvard University, delivered an address on this subject. The medical education of thirty years ago was contrasted with that of to-day. Passing to the advancements made in medical knowledge, he said they related chiefly to diagnosis, prevention, asepsis, and bacteriology. Medical education of the future would begin with preparation from the sixth year and graduation not before the twenty-fifth. Physicians should interest themselves in the public schools, and see that the course of study be of a nature to prepare children and youth for the practical affairs of life. The example of Johns Hopkins in demanding high educational qualification as preliminary to the study of medicine was commended.

President Eliot was tendered a vote of thanks for his most interesting, instructive, and brilliant address.

FIRST DAY—Evening Session.—Report of State Board of Medical Examiners.—DR. MORRIS J. LEWIS, of New York, read the report. During the year there had been 603 examinations, 8 before the eclectic board, 63 before the homeopathic board, 582 before this board. Licenses granted, 482; rejected, 171. The eclectics rejected 1, or twelve per cent.; homeopaths 8, or twelve per cent.; State board 162, or twenty-seven per cent. Many States had passed laws based on ours. Most State boards accepted a license granted by the New York board. It would be highly desirable if other States would adopt as high a standard as this, in order that licenses granted by them could be accepted here.

Since the last report most of the medical colleges in New York City had extended their course to four years, and soon, doubtless, this would be true of all

colleges in the State. The report was received and adopted.

Tetanoid Hysteria.—DR. GRACE PECKHAM, of New York, read a paper giving the histories of four cases of tetanoid hysteria, or possibly it should be called hysterical tetany, as the pathology of both tetany and hysteria was unknown. The diagnosis rested solely on the symptoms, and these were proteid and more or less similar in both. Pictures illustrating the contractures were shown. When the pathology was discovered the cases could be properly classified.

Treatment of Malignant Diseases in So-Called Cancer Institutions.—DR. NATHAN JACOBSON, of Syracuse, in this paper showed what looked much like charlatanry practised by certain so-called cancer institutions. They sent out circulars claiming that surgeons admitted their inability to cure cancer by the knife, that this treatment hastened the disease, while by escharotics, etc., these cancer specialists cured nearly all. Dr. Jacobson had been given the statistics of cures in one of these institutions by the husband of a patient. The institution claimed to cure cancer of the breast in severe cases in from three to five weeks. Yet ten cases there averaged eight months and all died. During their stay they simply underwent torture. Then the institution admitted many cases which were not cancerous.

The remarks in Dr. Jacobson's paper received the warm endorsement of Dr. Bulkley, Dr. Ely, Dr. J. N. Goff, and Dr. Schaffer. They had known of patients with cancer entering such places only not to return, while many patients admitted had no malignant disease at all.

Alcohol and Public Health.—DR. H. R. HOPKINS, of Buffalo, in some remarks on this subject condemned the recent addition to the law passed ten years ago, whereby it now was compulsory to give instruction in the public schools on alcohol and tobacco.

It was teaching pseudo-science, and tended to increase the long list of cranks.

DR. A. W. SUITER endorsed the remarks of Dr. Hopkins, and gave notice that he would offer a resolution in business session to-morrow, recommending the abolition of the law.

The Evolution of Pathology.—The last hour of the evening session was taken by DR. J. H. HUNT, of Brooklyn, in showing lantern slides of the fathers of medicine.

WEDNESDAY, JANUARY 29TH—*Morning Session.*

Report of Committee on President's Address.—DR. LUCIEN HOWE, chairman of the committee, read the report. It approved of the appropriation by the State of \$5,000 to the Medical Library, and recommended this amount as an annual appropriation. It recommended a "travelling" library; also efforts to establish harmony between this society and the American Medical Association; and that a special committee on expert medical testimony be appointed by the president. These recommendations of the committee were adopted. A long discussion took place on the question of holding meetings in Buffalo, N. Y., and elsewhere, and finally the matter was laid on the table.

Expert Testimony.—The committee on expert medical testimony reported through DR. RANSOM in favor of legislation directing the appointment of experts by courts, their duties to be advisory, and their reports to be made to the court, etc.

The report was adopted and the committee on legislation instructed to make efforts to secure the desired legislation.

Work of Health Boards Endorsed.—DR. VAN COTT, of Brooklyn, recited the benefits to the public of the work of health boards regarding vaccination,

infectious diseases, etc., and yet, he said, there had been suits brought against physicians for doing their duty. He offered resolutions approving of work of the boards. Adopted.

Regulation of Cancer Institutions, etc.—DR. L. D. BULKLEY offered the following, which was adopted:

"*Whereas*, Serious evils have often resulted to the people and profession from the existence and operation of private medical institutions for the treatment of cancer and other diseases;

"*Resolved*, That the committee on legislation be directed to secure, if possible, the passage of a bill by the legislature placing all such institutions under the care of the State Board of Health, in the same manner in which all private institutions for the care of the insane are under the care of the State Commission in Lunacy."

Alcohol and Narcotics.—DR. A. W. SUITER offered the following which was adopted:

"*Whereas*, This society is ever mindful of the evil results to individuals and to the community of the abuses of stimulants and narcotics, and is ever ready to co-operate with and encourage intelligent efforts to prevent such abuses; and

"*Whereas*, This society is familiar with the recent attempt to force upon our public-school system the task of teaching our children the chemistry, the toxicology, and the pathology of alcoholic stimulants and narcotic habits; and

"*Whereas*, The society is in entire sympathy with the probable motives of the promoters of this law, but has profound consideration of its inexpediency; therefore,

"*Resolved*, That the committee on legislation is hereby instructed to bring about the repeal or essential modification of the law relating to this subject."

Index Medicus.—DR. MILE, of Brooklyn, offered a resolution, favoring the publication of the *Index Medicus* by the national government. Carried.

Committee on Nominating Member of State Board of Medical Examiners.—THE PRESIDENT appointed Drs. F. C. Curtis, James D. Spencer, Charles Jewett, L. D. Bulkley, N. Jacobson.

This committee later recommended Drs. Fowler, of Brooklyn, and Wey, of Elmira; alternates, A. Walter Suiter and Willy Meyer.

Vaginal Hysterectomy by Clamps.—DR. WILLIS E. FORD, of Utica, in this paper described and advocated vaginal hysterectomy by clamps, these being preferred to ligatures. He did not agree with those who regarded hysterectomy as indicated in suppuration of the appendages. Vaginal hysterectomy was most called for in malignant disease.

Complications in Abdominal Surgery Implying Intestinal Anastomosis; Best Method for Operating.—DR. A. VANDER VEER, of Albany, recited three cases as a basis for his paper: 1, Woman with multilocular ovarian cyst of left side, papillomatous cyst of right side. Removal; intestinal adhesions; intestine tore; anastomosis by Murphy button; good recovery. 2, Strangulated hernia; many old and firm adhesions; loop of intestine gangrenous ten inches. Excision; Murphy button for end-to-end anastomosis; good recovery. 3, Laborer, acute interstitial hernia, gangrene of gut and spermatic cord. Testicle removed, intestine resected, etc; Murphy button; the patient died; some gangrene at button.

After discussing mechanical and non-mechanical means of anastomosis, Dr. Vander Veer concluded that in incised wounds of the small intestine or small gunshot wounds we still adhered to Lembert-Czerny or some other form of suture without mechanical device. The Murphy button had been well tested in anastomosis between gall bladder and intestine, between portions of intestine; with best results in the small intestine. There were some real dangers, how-

ever, connected with the button, among them fecal impaction, non-passage, gangrene. Maunsell's operation deserved consideration.

Sloughing Uterine Fibroids After Abortion and Labor.—DR. M. D. MANN, of Buffalo, in this paper related personal experience with fibroids complicating pregnancy, reviewed statistics, and gave conclusions. Personally he had looked upon sterility as the cause of the new growth, not as the result. Was operation necessary at all when pregnancy was complicated by fibroid?

Dr. Mann had in several cases expected to have to do Cæsarean section, but at labor only forceps were required. The danger of infection after abortion or labor was greater than usual where there was fibroid. Out of 597 cases in which nothing was done until labor, there had been 270 deaths. If sepsis developed it was exceedingly liable to involve the tumor, unless vigorous measures were employed. Expectancy was not justified after sloughing of the tumor had been recognized.

Technique of the Improved Cæsarean Section.—

DR. H. G. GARRIGUES read the paper. Strict antiseptics, four assistants; incision six inches, equal distance above and below umbilicus; seize uterus by left upper cornu, lift out, close incision partly above; place rubber tube around cervix, crossed but not tied, to be tightened as necessary. Incise uterus in median line, clamp bleeding vessels, avoid lower segment, incision four to five inches; if placenta is on anterior wall cut through it; if waters have not broken avoid soiling peritoneum. Introduce right hand, extract child by head if possible, if not by extremities; tie cord, divide, give child to assistant. Remove placenta if loose, if not insert sutures, but do not tie until placenta, now having loosened, is removed. Cervix should be open; silk No. 4 for deep suture in uterus, finer sutures for superficial, one suture for each inch; peritoneum united by broad surfaces. All sutures tied, elastic ligature gradually removed; abdomen closed. Do not curette uterus. Woman allowed up in three weeks.

DR. W. GILL WYLIE opened the discussion on the several papers, but limited his remarks to choice between vaginal and abdominal hysterectomy. His results had been good with vaginal operation, but he employed it in a much more limited class of cases than Jacobs and some others. Unless the tumors were small and easily reached through the vagina, he would open the abdomen. Morcellation by vagina on large tumors was not practised by Dr. Wylie. In some instances the operation was best started by vagina and completed by abdomen.

DR. BOLDT preferred ligature to clamp when the parts were within ready reach per vaginam. He believed in removing the uterus where the appendages were destroyed. In fixation in carcinoma of uterus, showing impossibility of removing all disease, hysterectomy was contraindicated.

DR. M. D. MANN thought the element of time did not often interfere with intestinal suture in preference to mechanical anastomosis.

DR. W. G. McDONALD showed Eastman's clamp and explained its use in vaginal hysterectomy.

DR. A. H. GOELET thought vaginal operation had only limited application.

DR. GOFFE gave some favorable experience with the vaginal method.

DR. A. T. BRISTOW said many cases of hernia reached the surgeon at a time when quick operation with little manipulation was necessary, and Murphy's button was here of special value.

DR. F. C. CURTIS preferred suture of intestine, unless haste demanded the button. There were weighty objections to the button, especially danger of its falling

into the stomach in stomach anastomosis. Lower in the bowel he had attached a suture to it, passed out through the anus, to secure exit of the button.

Early Diagnosis of Tubercular Kidney.—DR. WILLY MYER, of New York, in this paper, considered only chronic tubercular infection which primarily affected only one kidney. In his personal experience the left organ had been oftenest involved. Up to the time of degeneration of the tubercle there was likely to be no symptom attracting attention, except, perhaps, polyuria. When the case was first seen it might be necessary to make repeated microscopic examinations of the urine before tubercle bacilli were found. Inoculation experiments even might fail. A third test was to inject the patient with tuberculin, and several trials might fail, notwithstanding the existence of tubercular kidney. In the female, Kelly's was the best method for catheterizing the ureters. Caspar's ureteroscope was valuable in females as well as in males. After making diagnosis of primary tuberculosis of one kidney alone, the organ should be removed. If allowed to remain, the other organ was likely to become diseased.

The Symptoms and Diagnosis of Indigestion of Starchy Foods.—DR. R. W. WILCOX read this paper.

The diagnosis rested upon flatulence, sensory phenomena, constipation, general systemic disturbance, and urinary examination. In treatment, it was especially important to have thorough mastication of food, and drink at meals and much fluid food should be interdicted.

DR. BULKLEY confirmed the importance of avoiding fluids at meals, in order to allow the saliva to partly digest the starchy food.

SECOND DAY—Afternoon Session.—Congenital Dislocation of the Hip.—DR. HALSTED MEYER read the paper on this subject, and presented a patient showing good result of treatment. Hopper's and Lorenzo's open operations had given good ultimate results, and the mortality had been small, but not so small as with the subcutaneous method. These cases of deformity ought not to be sent away without treatment.

Preliminary Examinations.—DR. M. J. LEWIS stated that Dr. Jacobi had withdrawn his objection, which had yesterday led to the rejection of a part of the report of the committee on legislation, and Dr. Lewis now offered a resolution favoring legislation which would permit students entering colleges in the State before the law of 1895 went into effect, whereby the preliminary examination was made more difficult, to take the examination one year after matriculation. This was in order that the law might not be retroactive and do an injustice to students who had already sought admission under the law as it had previously existed, or injure our colleges. The resolution was adopted, after some opposition.

Discussion: Present State of Surgery of the Brain.—DR. E. D. FISHER read the first paper of a series on this subject. We should not be too hasty to operate where no good was to be accomplished. Early in this epoch the desire to operate had led surgeons to interfere in improper cases. Experience seemed to indicate that we could expose the brain to a great amount of manipulation, and even to extensive ablation, without endangering life. Indications were: Traumatism; localized epileptic seizures; athetosis, especially when associated with epilepsy and localizing cortex lesion; tumors; abscess; cerebral hemorrhage, especially meningeal; microcephalus.

The results of operations, according to statistics, were not favorable. One case of traumatic epilepsy, under Dr. Fisher's care, had been cured by operation three years ago. The operation, if undertaken at all, should always be made complete.

DR. M. A. STARR's paper appears in this issue of the MEDICAL RECORD (see p. 145).

The Value of Craniectomy and Its Indications in Conditions of Idiocy and Imbecility.—DR. C. L. DANA had collected eighty cases of craniectomy for idiocy and imbecility: improved, fifteen per cent.; deaths, five per cent.; unimproved, eighty per cent. Where improvement occurred, he thought it due to pedagogic influence.

Surgical Treatment of Epilepsy.—DR. SACHS being absent, Dr. Collins read the paper. Indiscriminate surgical interference was to be condemned. Recent traumatic cases and cases of local epilepsy furnished the classes for interference.

DR. JAMES W. PUTNAM, of Buffalo, also read on craniectomy, and cited one case of remarkable relief of epilepsy and idiocy by craniectomy, performed by Dr. Park. All cases considered, the percentage of improvement was small.

DR. GEORGE WOOLSEY, of New York, related his experience with craniotomy in eight cases. One of traumatic epilepsy was cured, one improved, the rest little benefited, if at all. More could be done in trauma of the skull by way of prevention of epilepsy by operative interference than by way of cure.

Heteroplasty to Cover Defects of the Skull.—DR. WILLY MEYER gave some of his experiences in this line, and recommended celluloid for covering defects in the skull.

DR. JOSEPH COLLINS said we had listened to papers which gave little encouragement in cerebral surgery, but there was one class of cases in which it offered the only hope, namely, cerebral abscess, limited or unlimited by sac—cases found mostly in purulent otitis.

DR. F. S. CREGO thought New York practitioners had gone to the opposite extreme from the position taken by them on cerebral surgery a few years ago. He believed in the middle ground, held by most German and English surgeons and neurologists. He had had a limited experience, with some favorable results.

DR. E. B. ANGEL held views in line with Dr. Crego, and also said he did not think it necessary to resort to heteroplasty, for a fibrous covering formed sufficient to resist injury, unless by puncture.

Treatment of Sciatica with Nitroglycerin.—DR. W. C. KRAUSS, of Buffalo, had had experience with nitroglycerin in seven cases of sciatica—three in private practice, large doses being used, and a cure had been effected in two weeks to three months. While the remedy might not be a specific, it deserved to be tried before other measures, to be replaced if it failed. Congestive headache and flushing of face, which large doses were apt to cause, could be prevented by bromides.

Deficient Excretion from Kidneys not Organically Diseased, in Some Disorders Peculiar to Women.—

DR. JAMES H. ETHERIDGE, of Chicago, read an address on this subject. A great many gynecological patients suffered from urinary insufficiency, and by relieving this we could relieve them of many nervous manifestations usually attributed to the pelvic organs. A woman weighing ninety pounds should pass at least five hundred grains of urinary solids daily; one weighing one hundred and eighty should pass eleven hundred grains. To estimate what should be the urinary solids, multiply the last two figures of the specific gravity of the whole urine for the day by the number of ounces voided, and that product by 1.10. If there were a deficiency of solids, there would be a deficiency of urea also.

The urea with the coloring matter constituted about two-thirds of the toxic principle of urine. Of the salts, chlorate of potash was most poisonous, and constituted one-third of the death-producing agents in so-called uræmia (Bouchard). The nervous manifestations in insufficient urinary secretion were the principal symptom. They varied in severity according to the fall of

solids: If to four hundred grains, the symptoms might be slight; if to three hundred grains, the symptoms became more striking; they were serious with a fall to two hundred grains, and threatened eclampsia at one hundred grains.

The gynecologist would find diuretics most efficient in the relief of many of his patients. There was also reason to believe that there was a close etiological relation between renal insufficiency and pelvic diseases.

DR. L. D. BULKLEY had found that many skin affections, and incidentally pelvic and nervous troubles, were relieved by diuresis. Acetate of potash was especially valuable, ten to twenty-five grains freely diluted in water.

SECOND DAY—Evening Session.—Report of Nominating Committee.—For *President*, Dr. James D. Spencer, of Watertown; *Vice-President*, Dr. L. D. Bulkley, New York; *Secretary*, Dr. F. C. Curtis; *Treasurer*, Dr. C. H. Porter; *Committee of Arrangements*, Dr. W. J. Nellis, Dr. W. Hailes, Dr. R. J. Wilcox; *Committee on By-Laws*, Dr. H. D. Wey, Dr. W. J. Harriman, Dr. F. C. Curtis; *Committee on Hygiene*, Dr. H. R. Hopkins, Dr. L. S. Pilcher, Dr. Daniel Lewis, Dr. W. G. McDonald, Dr. O. W. Peck, Dr. Lucien Howe, Dr. A. M. Campbell; *Committee on Legislation*, Dr. A. W. Suiter, Dr. M. J. Lewi, Dr. J. M. Winfield; *Committee on Ethics*, Dr. Charles Jewett, Dr. Eugene Beach, Dr. J. F. Heffron; *Committee on Prize Essays*, Dr. A. Jacobi, Dr. Henry Hun, Dr. M. F. Cheesman; *Committee on Publication*, Dr. F. C. Curtis, Dr. F. D. Bailey, Dr. M. D. Mann, Dr. C. H. Porter; *Delegates to the State and other Societies*: To British Medical Association, Dr. C. L. Dana, Dr. M. A. Starr, Dr. J. P. Boyd, Dr. J. P. Bigelow; to Canadian Medical Association, Dr. A. B. Miller, Dr. C. L. Parkhill, Dr. T. S. C. Van Allen, Dr. G. M. M. Combes, Dr. W. Phillips, Dr. E. H. Bridges, Dr. E. L. Mooney, Dr. P. Collard; to Ontario Medical Association, Dr. M. D. Mann, Dr. Roswell Park, Dr. F. S. Crego, Dr. N. Jacobson, Dr. J. O. Roe, Dr. T. O. Taft, Dr. M. A. Barney, Dr. G. H. Oliver, and a number to different State societies. It was suggested that the secretary be empowered to add to the list of delegates. The report was signed by the following gentlemen of the nominating committee: Dr. M. D. Mann; 1st district, Dr. C. W. Townsend; 2d, Dr. Philander Collard; 3d, Herman Bendell; 4th, Dr. Charles M. Lefler; 5th, Dr. W. A. Vincent; 6th, Dr. D. G. Burr; 7th, Dr. E. L. Mooney; 8th, Dr. F. S. Crego.

THURSDAY, JANUARY 30TH—*Final Session.*

The report of the nominating committee was confirmed and all the nominees declared elected.

Reorganization of the Coroners' System.—DR. W. G. MACDONALD read this paper. The annual cost of the coroners' system to the State has been over three hundred thousand dollars. Its administration was incompetent. The German system was commended. It consisted of a physician, a surgeon, and a judge for each of several districts.

DR. RUDOLPH WITTHAUS reported for the special committee on coroner's system, acting with the committee on legislation and that of the State Bar Association. They hoped this winter to have a bill passed, substituting for the present coroners' system one whereby a medical examiner is to be appointed by the Supreme Court for each of the several districts.

HON. TRACY BECKER, ALBERT BACH, and HERMAN BENDER warmly advocated the proposed change, and a motion to continue the special committee and appoint an auxiliary committee of twenty-five or fifty was adopted.

DR. BROWNING, of Brooklyn, read a paper on the

development of muscular atrophy on a basis of old infantile spinal paralysis. Disease, poor innervation, unequal development, and cold, were active factors in production of subsequent atrophy.

DR. VEEDER, of Lyons, read a paper on neuritis, complicating dislocations of shoulder and elbow. For treatment, use care in making reduction; subsequently give electricity, massage, etc., for the neuritis.

DR. WILLIAM HAILES, of Albany, reported two cases of difficult perineal and suprapubic lithotomy. Other papers were read by title.

Therapeutic Hints.

Diphtheria.—

No. 1.

R Tinct. aconiti.....gtt. xx.
Tinct. belladonnae.....3 ss.
Glycerini.....3 iv.
Aque gaultheriae.....ad 3 iv.

No. 2.

R Potass. chloratis,
Sodii bromidi.....āā 3 ss.
Glycerini.....3 ss.
Tinct. ferri chlo.....3 ss.
Aque.....ad 3 iv.

Dose: Half a teaspoonful for an adult.

These are to be given alternately every half-hour, thus bringing the doses fifteen minutes apart.—DOUGLAS.

A Depilatory.—

R Iodine.....1.5 grams.
Essence of turpentine.....40 drops.
Castor oil.....4 grams.
Alcohol.....20
Collodion.....Enough to make 60

Apply every day for three days.

—LESC.

Lobar Pneumonia, Causes of Death In.—1. Death from insufficiency of the pulmonary function. 2. Death from the severity of the infection. 3. Death from complications—meningitis, pericarditis, gangrene of the lungs, etc. 4. Death dependent on heart failure. Here we must differentiate the insufficiency of the heart, weakened and defective, before the beginning of the pneumonia from the secondary cardiac weakness dependent on the pneumonia.—BOLLINGER.

Parasiticide.—

R Spirits of camphor.....4.200 grams.
Glycerin.....1.000 "
Essence of turpentine......180 "
Mercury bichloride.....6.000 "

—HALLOPEAU.

Ether Narcosis.—The proposal of Laborde that respiratory movements could be induced, when they had entirely ceased, by rhythmical traction upon the tongue, has called forth a host of testimonials to the success of the method.

Antitoxin.—Bettman says: 1. That the antitoxin does undoubtedly affect favorably a large number of diphtheria cases. 2. That it is the duty of physicians to use the antitoxin early in every case of severe diphtheria occurring in children. 3. That the mortality from diphtheria is destined to be largely diminished by prompt use of the antitoxin.

Loeffler Bacillus.—(1) The Loeffler bacillus was present in each one of the fifteen cases of diphtheria examined; (2) by means of pure cultures of the bacillus there were reproduced false membranes in animals, just as Loeffler had done; (3) With pure cultures paralyzes in animals were produced similar to the post-diphtheric paralyzes in man; (4) The bacil-

lus gives rise to poisonous products which, when injected into animals, produced either death or paralysis, according to the dose.—ROUX AND YERSIN.

Hay Fever.—

R Liq. pot. arsenitis,
Ext. nucis vomice fl.,
Ext. cinchonae fl. (detannated).....āā 3 vi.
Alcoholis.....3 iij.
Syr. aurantii.....q. s. ad 3 xvi.

M. Sig. One to two teaspoonfuls, taken three times daily, with or after meals.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEETING OF THE FELLOWS OF THE ROYAL COLLEGE OF SURGEONS—REPRESENTATION OF MEMBERS—ADMISSION OF WOMEN—OBSTETRICAL SOCIETY—RELATION OF THE OVARIES TO OSTEOMALACIA—LACTATION IN RELATION TO MENSTRUATION AND PREGNANCY—A NURSE POISONED BY CARBOLIC ACID.

LONDON, January 10, 1896.

Two rather important concessions were made at the meeting of the Fellows of the Royal College of Surgeons, on the 2d instant, and have occupied the chief place in the conversation of the week. The first resolution adopted was "that it is desirable to give the members of the college direct representation on the council." There was an attempt to define the extent and nature of this representation, but eventually all details were omitted, and this vague resolution carried. It should be understood that the resolution decides nothing. It is merely the expression of an opinion which the council is at liberty to disregard or to discuss. It has, however, some weight as the expression of the views of a meeting to which the council had referred this and other questions for discussion. Of course, there was a protest on behalf of the Fellows who do not like to abate their privileges, but it is satisfactory to find that the claims of justice were recognized in a meeting of the privileged class. It is true that only a small number of Fellows was present, but the meeting being legally constituted and full notice of the proposal having been given, those who stayed away have no ground for complaint. How far the decision would be endorsed if the Fellows were to vote by proxy does not appear, but the members consider they have gained a step and are encouraged to persevere. There are those, too, within the council who are favorable to the representation of members.

The second question was as to the admission of women to the diplomas of the college. Here, too, the advocates of a change were victorious—forty-five Fellows voting for the admission of women and ten against. After their recent rebuff at the sister college, this seems to the ladies a considerable advance and a proof that the struggle will soon end in their complete triumph. The result has been attained by dogged perseverance, and illustrates the adage about woman, "if she will, she will, you may depend on it."

The council will have to consider this subject rather carefully, in connection with the agreement between the two colleges. It is not a question of admitting women to the profession—that has been settled this long time—but, shall they enter through this college? The council would like to take their fees and the consultants encourage them. Whether the general practitioners are anxious to bring in more competitors for their scanty rewards "is another story."

After this vote was taken, there was a general stampede and the meeting came to an end, as the necessary quorum of thirty did not remain.

The Obstetrical Society resumed work on New Year's Day, when a paper by Professor Curatula, of Rome, was presented, on the influence of the removal of the ovaries on metabolism in its bearing on osteomalacia. Experiments were recorded tending to support the hypothesis that the ovarian secretion had a moderating influence on the development of the skeleton, so that their removal would entail a larger retention of organic phosphorus, and, therefore, a greater accumulation of earthy salts in the form of phosphates, until the skeleton should become normally solid. The

injection of ovarian juice in castrated animals increased the elimination of phosphorus, which the operation diminished. It was further stated that the elimination of carbonic anhydride was also decreased by removal, which may assist in explaining the increase of fat which occurs. Considering the relations which have been shown to exist between thyroid and other glandular hypertrophies to disease, we may admit that some influence is probably exerted by the ovaries, though it remains to be seen whether Professor Curatula has shown what the influence is. Dr. Griffiths remarked that on the continent osteomalacia occurs at a comparatively early period. But there are one or two specimens in museums showing that it may occur early in this country, although it is almost exclusively a disease of old age with us. Moreover, it may occur in the male. Mr. B. Sutton said the cases alluded to were changes of a senile kind, and differed greatly from true osteomalacia, which is an acute disease of the child-bearing period of woman's life, but he did not deny that it might occur in man. Dr. Duncan attributed the cases occurring in the young to the results of rickets in childhood.

Another obscure topic was taken up at this meeting, viz., the effects of lactation on menstruation and impregnation. This was introduced by Dr. Renfry, who had collected the history of some nine hundred lactations. The figures seem to support the common belief that lactation renders pregnancy less probable, but not to the extent of prevention. The recurrence or otherwise of menstruation while suckling has an influence on the probability of impregnation. The statistics submitted showed that in only fifty-seven per cent. were the menses absent, while in forty-three per cent. they were more or less present, including twenty-six per cent. in which there was complete regularity. The probability of impregnation during lactation was six per cent. with absolute amenorrhœa; rising to sixty per cent. with absolute regularity of menstruation. Suggestions were made as to functional association between the mammæ and the uterus, as to the renewal of the mucous membrane, and as to involution, but none of these suggestions commanded full acquiescence, and this is but natural, considering how limited is our knowledge on some of the points involved.

A sad case of poisoning by carbolic acid has been added to the long roll of deaths due to that article. A nurse at the Glasgow Royal Infirmary, wanting a dose of castor-oil, took the bottle of carbolic acid instead, and poured out and swallowed the poison. How an experienced nurse should make such a mistake and not detect the smell of the acid seems strange. Keeping the poison close by the oil, and apparently in similar bottles, indicates bad management. The nurse was a lady of education, daughter of a bishop, and a favorite in the infirmary, where she had worked several years.

Dispensary Beats.—There is one feature of the dispensary abuse question, says the *Pittsburg Medical Review*, which seems to have escaped the attention of the complainants, namely, that persons able to pay, but who through misrepresentation obtain medical advice and medicine gratuitously at charitable institutions, are dishonest and would consequently prove unprofitable patients to those physicians who imagine themselves defrauded every time a patient passes through the door of a free dispensary. When it is remembered that dishonest persons are an integral part of every large community, and that we have them with us always, just as certainly as we have the poor, it is not surprising that some obtain free service to which they are not entitled.

Condensed milk should have ten per cent. of fat.

OUR VIENNA LETTER.

(From our Special Correspondent.)

PHOTOGRAPHY OF THE INVISIBLE—ROENTGEN'S DISCOVERY OF THE TRANSMISSION OF CERTAIN RAYS THROUGH SOLIDS—PROF. EXNER GIVES A DEMONSTRATION—PROF. ROENTGEN EXHIBITS HIS METHODS TO THE GERMAN EMPEROR—SERO-THERAPY OF DIPHTHERIA.

VIENNA, January 13, 1896.

ROENTGEN'S discovery of the transmission of certain rays through solids, announced at the recent fiftieth session of the Berlin Association of Physicists, bids fair to mark an epoch in natural science, and promises great utility in medicine. The greatest interest has been aroused, and Vienna physicians in attendance at the session on January 10th of the Imperial Medical Association were favored by Professor Exner with a demonstration of the results already published by the discoverer. The principle involves the utilization by photography of the cathodal rays emitted from a Geissler's tube. Roentgen found that these rays (named by him "X-rays"), invisible to the human eye, possessed also the property of transmission through some solid objects, such as wood, paper, and a few metals, while they were intercepted by others. The interposition of a sheet of paper was without effect; a slightly perceptible interruption was produced by a playing card; a plain diminution of intensity followed the intervention of a pack of playing cards, but a book of one thousand pages did not entirely absorb the cathodal rays. The rays also passed, in part, through a sheet of aluminium one and one-half centimetres in thickness, and this metal was found to possess greater transmissibility than glass, calcspar, or quartz. Exner exhibited a photographic plate, upon which, after exposure to the "X-rays," were shown the outlines of a Siemens element, enclosed during the process of photography in a wooden box. The great possibilities of the discovery were revealed by a photograph of the bony skeleton of the living human hand, with a finger-ring but without the soft tissues. Roentgen advances the theory that the "X-rays" are longitudinal, resembling ether waves, and not transverse, as are light waves.

Upon invitation Professor Roentgen yesterday demonstrated his discovery at Berlin in private audience with the German Emperor, who afterward conferred upon him the Order of the Crown, Second Class.

Serum Treatment of Diphtheria.—At the St. Anna's Children's Hospital, 890 patients have been submitted to the serum treatment during a period of thirteen months. The mortality from diphtheria during the preceding thirty-three years was 42.8 per cent. Under the serum treatment the mortality has been reduced to eighteen per cent. In this percentage have been included all cases—those received in moribund condition and terminating fatally within an hour or two, and also those complicated by other diseases, among which scarlatina and tuberculosis have been prominent. Upon the completion of one thousand cases, a detailed report will be published by Professor Widerhofer in the *Jahrbücher für Kinderheilkunde*. This report will show that, with the elimination of the complicated and previously neglected cases, the mortality will be reduced to about twelve per cent. It will further reveal an insignificance of complications arising from the use of the serum, reduction of the number of operated cases, and general diminution of the severity of the disease, both in limitation of the membrane and in the subjective condition of the patient.

In consequence of the scarcity of physicians in the low lands, the Lower Austria Landesanschluss has had under discussion the need of further provision, and has submitted to the diet a resolution asking for the

immediate consideration of their needs, and proposing Linz as the most available location for an additional medical faculty.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 25, 1896:

	Cases.	Deaths.
Tuberculous.....	160	125
Typhoid fever.....	12	5
Scarlet fever.....	195	23
Cerebro-spinal meningitis.....	3	3
Measles.....	430	21
Diphtheria.....	279	48
Small-pox.....	0	0

The Trials of Country Medical Practitioners in France.—The English parish medical officer is wont to deem himself—and not unreasonably so—the worst-used individual in existence. A stipend that a laborer would spurn, a mass of work that the same laborer would never consent to perform, unjust criticism on the part of guardians who have no conception of the dignity appertaining to our calling—these and a thousand and one other miseries would suffice to break the heart and sap the courage of a member of any other profession. This state of things is not, however, peculiar to the British Isles, unless the experiences of Dr. Boyron, of Amagne, are exceptional. This gentleman had the misfortune to be a club medical officer, and the mayor treated him accordingly much as he would treat a gamekeeper. Dr. Boyron was the medical officer of a village Société de Secours Mutuels, and he found that, encouraged by the peasant-mayor, his club patients acquired the habit of treating him in a very cavalier fashion. He mentioned the matter to the mayor, who seemed to enjoy the joke immensely. The medical man thereupon resigned. The combative mayor, however, maintained that a club medical officer had no right to resign, and even had the assurance to contest (unsuccessfully) the legality of the resignation at headquarters. One day a station-master sent an urgent messenger for Dr. Boyron, who, on his arrival, found that the railway official had sent for him, not to ask his advice, but to tell him that he was being treated by a neighboring priest, whose prescriptions he was requested to countersign, so that the company could be charged with the furnishing of the drugs. Listen to yet another story. A young medical man settles in a commune whose paupers he attended for \$10 per annum. One night, soon after his arrival at this Eldorado, he received an urgent summons to visit a patient who lived at a distance of six kilometres from the village. On reaching the cottage—it was then 11 P.M.—he found the doors closed and lights extinguished. In reply to his knocks the door was opened by a sturdy peasant, who laughingly informed him that there was no illness in the house, but that his wife had wished to see if, when any one was ill, he would come if sent for! The unfortunate medico—since dead from overwork, and probably under-feeding—remarked, "I could have felled him to the ground." Added to these annoyances, others of political origin are quite common in rural France. Our Gallic brethren meddle a good deal in politics, and as their tendencies are generally toward radicalism they have often *maillé à partir avec le curé*. Altogether, I should say that the British country medical practitioner has the best of it.—*Paris Cor. Lancet*.

Sunshine and Life.—Sunshine has long been credited with possessing therapeutic powers, and, indeed, traditions of cures effected by the ancients by means of insolation have been treasured up and handed down to the present day. Even as late as the beginning of the present century we may read of a French physician seriously recording his claim to have cured a dropsical patient within two weeks by placing him daily for several hours in the sunshine, and many medical journals of recent years contain communications on the beneficial results derived from the use of sunshine in the treatment of various diseases. It seems curious, therefore, that while so much has been done to test the action of light on disease microbes in artificial surroundings, such as are to be found in laboratory experiments, hardly any investigations have been made to try and define more precisely how sunshine may affect their pathogenic action within the animal system. Dr. Masella's researches, undertaken with the express object of, if possible, elucidating this question, are, therefore, of special interest and importance. The first series of experiments was carried out to ascertain whether exposure to sunshine increases or reduces an animal's susceptibility to particular diseases, those selected for investigation being typhoid fever and cholera. For this purpose guinea-pigs were exposed to the full rays of the sun during a period of from nine to fifteen hours for two days, while other guinea-pigs, for the sake of comparison, were not permitted to have more light than that obtainable in a stable where only diffused light was admitted. Both these sets of animals were subsequently infected with virulent cultures of cholera and typhoid germs respectively, and were in neither case exposed to sunshine. The results which Dr. Masella obtained were remarkable, for he found that those animals which, previous to infection, had been placed in the sunshine, died more rapidly than those which had been kept in the stable, and that the exposure of the sun's rays had so increased their susceptibility to these diseases that they succumbed to smaller doses, and doses, moreover, which did not prove fatal to the other guinea-pigs. Still more striking was the part played by isolation in the course of these diseases in animals exposed to sunshine after inoculation, for instead of dying in from fifteen to twenty-four hours, they succumbed in from three to five hours.—*Longman's Magazine*.

A "miraculous" cure has recently occurred in Moscow, where it has caused considerable excitement. It is, perhaps, a more than usually interesting instance, and therefore deserving of the permanent record given to it by Professor Kozhevnikof, who gave the details of the case at the last meeting of the Society of Neuro-Pathologists in Moscow. The professor had not had the patient under his treatment, but had seen him more than once both before and after the "cure." The patient, N. D—, was a lecturer in the Moscow University. He had suffered from a severe form of sycosis menti since June, 1894, for which he underwent treatment at the hands of various specialists—among others, of Professors Kaposi, of Vienna; Schwimmer, of Buda-Pesth; Lassar, of Berlin; Pospislof, of Moscow; and Stukovenkof, of Kiev. In April last he returned to Moscow; his chin was then covered with a freely suppurating eruption. He now sought the advice of a "wise woman," an attendant at the baths, who was in the habit of giving herbs and "simples" to her clients. In this case no such remedy was employed. N. D— was told to meet the woman next morning at five o'clock in the Temple of the Saviour, the colossal church on the Moskva River, which has been building all the century and is yet incomplete, in memory of the famous events of 1812. He came as told, and, while he re-

mained a passive onlooker, the woman prayed for three or four minutes; the same thing was repeated that evening and again the following morning. But in the mean time the eruption on N. D—'s face had begun to improve; the discharge ceased, the swelling subsided, and in twenty-four hours scarcely a sign of disease was left. Such are the facts as given by the patient himself and confirmed by Professor Kozhevnikof. The professor, however, adds some important points bearing on the case: The patient is of neurotic temperament; his sister is highly hysterical; he had frequently had boils on both arms, with a marked tendency to symmetry in position; and the sycosis itself showed some signs of being, if not of nervous origin, at least under nervous influence. The impressive surroundings under which the "cure" was wrought, and the mysterious cabalistic prayer—which the woman refused to divulge, "lest it should begin to act with the person to whom she told it and cease to act with herself"—are also factors to be remembered in connection with the neurotic and impressionable character of the patient.—*British Medical Journal*.

Memory and its Loss.—Two recent cases have directed popular attention to one of the most mysterious results of altered cerebral function—an absolute loss of that which is called "memory." The symptom is so striking, so conspicuous, and so simple that it is natural for it to attract attention, and natural, also, that it should seem to be, in some way, susceptible of explanation. But, in truth, it is one of the derangements which bring into prominence the cerebral function of which we know perhaps less than we do of any other. There are two elements of the process which is included in the term "memory." They are generally confused, although one is often distinguished as "recollection." That which we call "recollection" is the voluntary use of memory; and it is the power of the will over memory, and not memory itself, which is lost in such cases as those which have recently attracted attention and of which instances are familiar enough in medical science. The physical basis of memory rests on the fact that every functional state of the brain leaves behind it a residual condition, in consequence of which that precise condition, in the same degree and the same combination, is more readily reproduced. The tendency for the state to occur again is the greater the more frequently it has previously occurred. It is this law which, of course, underlies all physical education, as well as all memory, commonly so termed. The occurrence of special nerve-processes in association with each other leaves behind a tendency for the recurrence of the association, so that one "idea" causes the revival of another. The physiologist and the physician are mainly concerned only with the physical processes in the brain which correspond to and accompany the mental processes with which they, as physicians or "physical physiologists," have less to do. But with these is combined the influence of revival of past activity, which is itself subject to the determining power which we call the "will." This association has baffled, and must apparently forever baffle, our scrutiny. It is far beyond the range through which science can penetrate. We know of its workings by subjective facts on the one hand, and on the other by its effects. Among these effects is the susceptibility of the renewal of past brain processes to the will. We can voluntarily recall the impressions of the past, we can induce the same combinations of nerve action, but how we know not. True failure of "memory" can only be assumed in the cases in which there is a general depreciation of the cerebral functions. In consequence of impaired nutrition of the brain, the functional states do not leave the due residual effect which facilitates their

revival. The change may be compared to the difference in the depth and in the permanence of the furrow in soils of different cohesion when the ploughshare cuts into them. On sand, for instance, as a much-quoted phrase reminds us, the ploughshare, instead of leaving a permanent furrow along which it can, if necessary, easily glide again, makes only a slight depression, almost at once filled up by the non-coherent particles from the crests. Such failure of memory is seen in old age, in general degenerations of the brain tissue, and also, in a striking way, in some cases of cerebral anæmia. In profound deficiency of the blood, qualitative or quantitative, the state of the brain may be such that no mental impression leaves an enduring trace such as can permit its reproduction. In such conditions there is a true failure of memory. But we cannot assume that this is the case when there is only a simple loss of the power to revive past impressions by the will, such as occurs as the result of sudden local disease or sudden injury. A severe concussion may be followed by a period during which there is unconsciousness, and afterward by a return of an apparently normal mental state. Everything up to the moment of the accident may be recollected, but everything afterward may be an absolute blank. Even if the sufferer soon regains consciousness and appears to be in normal mental vigor, the residual states left by his mental processes are not within the power of will to recall. Such sudden change—probably, in some cases at least, a sudden local lesion—limits the power of the will in a curious way. The will can induce the revival only of those processes which occurred a long time previous to the alteration. It is a well-known fact that the earlier in life cerebral processes occur the more easily are they revived. After middle life the difference in the intensity of the residual states, or perhaps some difference in their relation to the mysterious influence of the will, makes them so much less amenable that such a sudden alteration as may be caused by a local lesion will withdraw them from the influence of volition. This can scarcely be spoken of as true loss of memory: it is loss of voluntary recollection, and that is all we can say. Strange, indeed, is the apparent slightness of the cerebral influence which, like a gearing apparatus, keeps within the power of the will these residual states. Who does not know how a vivid dream may be recalled by some chance incident, revealing that an apparently dreamless night was filled with activity. In the curious brain state which follows a slight epileptic fit, in the state of "automatism," as it is termed, residual states must be produced as definite and as deep as any which occur in normal conditions, but they are beyond the power of the will and of any association to reproduce them. In a case recorded by Dr. Gowers, a carman drove his van across London, steering his way with precision through the crowded streets, and then suddenly found himself six miles distant from his destination. During the hour which had elapsed innumerable incidents must have left impressions deep enough to have enabled them to be reproduced at once by a voluntary effort, were it not for the sudden breaks in the continuity of consciousness which occurred, first, when he, as the saying is, "lost himself," and secondly, when he "came to himself." Rarely, in some like state at a subsequent period, the connection with the past may be re-established. As a rule, in this morbid state, the missing link in the mechanism of voluntary recollection is never re-established. But it is otherwise when there is a sudden loss of the power of the will over the residual states produced under normal conditions, but which have been separated from volition by some sudden change. In such cases as those which have been discussed so much of late in the

daily press, the residual states are there, and, at some link in the chain of association which exists between them, a renewal of the lost influence may occur, and may then quickly spread through the whole series; the memory may suddenly give signs, quickly increasing, of returning susceptibility to the will, which we call the power of recollection—a word which seems so simple, and yet denotes the greatest mystery of brain and mind.—*Lancet*.

To Abolish the Breast.—At a recent meeting of the German Social Democratic party, it was proposed by an enthusiastic reformer that the State should prohibit wet-nurses on the ground that sterilized milk was preferable to Nature's article. Better still, we should substitute for the pregnant woman a sterilized ovum incubator.

"I'm Sick."

I'm sick of gruel and the dietetics,
I'm sick of pills, and sicker of emetics,
I'm sick of pulses' tardiness or quickness,
I'm sick of blood, its thinness or its thickness,
In short, within a word, I'm sick of sickness.

—HOOD.

Hypnotism a Valid Defence.—The Russian Court of Appeals a few days ago commuted the sentence of death imposed upon a girl named Remyantzeff to five years' imprisonment, on the ground that she was hypnotized. The evidence showed that the girl was completely under the control of a man who compelled her to poison her father.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

AN ATLAS OF THE NORMAL AND PATHOLOGICAL NERVOUS SYSTEMS. By Dr. Christfried Jakob. Translated by Joseph Collins, M.D. 8vo, 232 pages, 220 figures on 78 plates, principally in colors. William Wood and Company, New York (Wood's Medical Hand Atlas Series).

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XIII., 8vo, 516 pages, illustrated. Printed for the Association.

STUDENTS' AID IN OPHTHALMOLOGY. By Gertrude A. Walker, M.D. 8vo, 183 pages, illustrated. Price, \$1.50. P. Blakiston, Son & Co., Philadelphia, Pa.

THE FUNCTIONAL EXAMINATION OF THE EYE. By J. H. Claibourne, Jr., M.D. 8vo, 100 pages, illustrated. The Edwards and Dooker Co., Philadelphia, Pa.

GOODSELL'S POCKET ANATOMY. By F. W. Goodell, M.D. 12mo, 154 pages. Published by the author at Effingham, Ill.

THE MEDICAL NURSE. By John F. B. Lillard, 12mo, 141 pages. I. E. Booth, New York.

DENTAL MATERIA MEDICA AND THERAPEUTICS. By James Stocken, L.D.S. Fourth edition. 12mo, 155 pages. J. H. Vail & Co., New York. Price, \$1.25.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. Volume VI.—Diseases of the Respiratory Organs. 8vo, 697 pages, illustrated. William Wood and Company, Medical Publishers, New York. Prices: muslin, \$5.00; leather, \$6.00; half morocco, \$7.50.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE, AND TOXICOLOGY. By R. A. Witthaus, A.M., M.D., Professor of Chemistry, Physics, and Hygiene in the University of the City of New York, etc., etc., and Tracy C. Becker, A.B., LL.B., Counsellor-at-Law and Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo. Volume III. 8vo, 743 pages, illustrated. SIGNIFICANCE OF PLEURISY, AND SOME POINTS IN ITS TREATMENT.¹

By EGBERT LE FEVRE, M.D.,

ADJUNCT PROFESSOR OF MEDICINE, MEDICAL DEPARTMENT UNIVERSITY OF THE CITY OF NEW YORK; ASSISTANT VISITING PHYSICIAN BELLEVUE HOSPITAL; CONSULTING PHYSICIAN BETH ISRAEL HOSPITAL.

MR. PRESIDENT AND MEMBERS OF THE SOCIETY: Whenever we encounter a case of pleurisy, the questions that present themselves are: What is its significance? What are its etiological factors? Can it be considered a primary pleurisy by infection, or does it belong to the secondary form, or pleurisy by propagation or extension? What is the relation of primary pleurisy to pulmonary tuberculosis, and do statistics bear out the statements that are so often made, that an attack of pleurisy almost always predisposes the patient to the dangers of pulmonary tuberculosis?

In order to answer these questions it is necessary to consider briefly the structure of the pleura. The pleura, pericardium, peritoneum, and tunica vaginalis are derived as constrictions from the embryonic single pleuro-peritoneal cavity first formed. These serous cavities are to be regarded as parts of the general lymphatic system, and, indeed, the serous fluid which they contain is in reality "lymph." By stomata the pleural cavity is put into communication with the lymphatics, not only of the diaphragm (on its pleural surface), but also of the lungs and the thoracic walls; and during the movements of breathing, the contents of the pleural cavity are continually being pumped away, partly into the lymphatics of the lungs, partly into those of the diaphragm and chest walls. The quantity of fluid is, at any one time, in normal conditions very small, but that fluid appears to be continually renewed, old fluid passing away to the lymphatic system and new fluid taking its place.²

In considering the etiology of diseases of the pleura, I think the most comprehensive classification for our purpose is:

I. Pleurisies by propagation.

II. Pleurisies by infection.

The first group take their origin from lesions of the thoracic walls, thoracic organs, or neighboring viscera. Among the lesions of the thoracic walls that may induce inflammatory disease of the pleura, it is necessary to mention only osteo-periostitis, costal caries, parietal phlegmon, and even cancer of the mamma. The diagnosis of these primary lesions is not difficult, and their relation to the subsequent pleurisy is readily understood when we consider the close relation that exists between the lymph channels of the chest wall and the pleura.

Diseases that involve the structures and organs of the abdominal cavity, especially the upper portion, are liable to cause a pleurisy. The diaphragm does not form an impassable barrier to the extension of inflammatory processes. The diaphragm may remain

intact, the virus spreading through the lymphatics, or there may be necrosis and perforation. When the diaphragm is intact, the nature of the pleurisy may be simply adhesive, obliterating the lower part of the pleural sac, or it may be plastic, serous, or purulent. When there is perforation of the diaphragm the process in the pleura is generally of the same nature as that below the diaphragm. The subdiaphragmatic diseases that are most likely to cause involvement of the pleura are acute hepatitis and perihepatitis; abscess and hydatid cysts of the liver, especially when they involve the convexity; atrophic and hypertrophic cirrhosis; subphrenic abscesses (of all kinds); inflammation of the spleen. More infrequent are those abscesses and inflammations that extend from organs lower down in the abdominal cavity, as the appendix vermiformis, ovaries, etc.

When we come to consider the relation of pleurisy to diseases of the lungs, many facts must be taken into consideration. Affections of the portions of the lung immediately in contact with the pleura almost always set up an inflammation in that membrane, which may express itself as a simple adhesive type, or may be attended by a fibrinous, serous, or purulent effusion. The dependence of these secondary forms on primary diseases of the lungs, as lobar and lobular pneumonia, pulmonary tuberculosis, infarctions, abscesses and gangrene of the lung, or diseases of the bronchial glands, is so evident as to need no explanation. When, however, the pre-existing disease of the lung does not approach the surface, or the pleurisy is at a widely distant point, or even on the opposite side, the relation is not so evident. We can more easily understand the liability of the pleura to become affected if we study its relation to the lymphatic system of the lung.

This relation is best seen in the infection of the lung that takes place in anthracosis, and, furthermore, shows the route the infectious and irritating matter takes when inhaled into the pulmonary tract, or when a quiescent and perhaps unsuspected focus of tuberculous infiltration breaks down and discharges its contents into the bronchi. When the upper air passages are in a normal condition, most of the dust is caught on the mucous membrane of the trachea and larger bronchi and removed, together with the phagocytes, as expectoration. Those particles that penetrate into the smaller bronchi, infundibula, and air vesicles pass through into the stroma of the air vesicles, peribronchial lymphatics, and especially into the large perivascular branches. Those which enter the peribronchial lymphatics apparently very soon pass into the large lymphatics around the arteries. From the perivascular lymphatics they run into the lobular septa, from these to the deeper layer of the pleura, and ultimately reach the bronchial glands. The superficial layer of the pleura is not injected. The well-marked injection by carbon particles can be seen only in the lungs of coal-miners and those who have worked for a long time in a dusty atmosphere; yet all have seen at autopsies the pigmentation immediately under the pleura, which gives the lungs their mottled appearance, and which also shows the tendency for particles of dust to be arrested in these regions.

¹ Read before the Medical Society of the County of New York, January 27, 1896.

² Foster's "Text-book of Physiology," 5th edition, p. 489.

During the past few years, medical literature has teemed with articles showing the infectiousness of dust, so that it is no exaggeration to say that we are exposed daily to its dangers. It also emphasizes the resistance that the tissue of the pulmonary tract has to infectious agents, and shows the ease with which rapid diffusion of the virus to the subpleural lymph spaces, and the subsequent inflammation of the pleura itself, may occur when this resistance is lost and the barriers are removed.

Dr. C. G. Coakley has kindly placed at my disposal results (as yet unpublished) obtained in a series of experiments conducted at the Loomis Laboratory. A solution of India ink was made, and passed through three thicknesses of filter-paper. The individual particles held in solution were very small (less than the size of the eosinophile granulations in white blood corpuscles). Ten cubic centimetres of this filtered solution were injected into the trachea of rabbits, and the animals killed in from fifteen minutes to two hours. It was found in every case (whether fifteen minutes or two hours had elapsed) that not a trace of the pigment could be found in the trachea, bronchi, and alveoli, but all had been absorbed. Except where a few lymph cells had ruptured, no free pigment was found in the lymph channels, but was contained within the lymph cells or phagocytes which were scattered through the lymph channels of the lung, underneath the pleura, and in bronchial glands (deeply pigmented). Infectious agents, other than dust, may be taken up by the lymph cells, and if not destroyed be retained in the lymph glands without producing any active lesions. An interesting series of observations on the long retention of virulent tubercle bacilli in healthy bronchial glands (glands enlarged only) has been reported by Dr. H. P. Loomis.¹

This brings us to the question, What proportion of acute pleuritis is tuberculous? The nature of the pleuritis secondary to diseases of the thoracic walls, abdominal organs, or to pre-existing pulmonary diseases, is usually easily determined. When, however, those belonging to the infectious group are considered, the difficulty in deciding is very great. It is interesting to note the opinions of various writers on this subject. Landouzy and his pupils, Joanne and Mayor, hold that all cases of acute pleurisy are tuberculous. Strümpell considers a non-tuberculous, simple, fibrinous, or exudative pleurisy a rare disease, and believes that if phthisis comes on several years later it is probably due to the pleurisy, and that it is very uncommon for the symptoms of acute tuberculosis or chronic phthisis to appear as an immediate result.

Germain Sée believes that seventy-five per cent. of all acute cases are tuberculous—in fact, regards pleuritis as patients affected with tuberculosis in the evolutionary stage.

Anstie says: "It is now well established, not only that pleurisy occurs in phthisis, but that pleurisy can set up true tuberculosis, even in perfectly healthy subjects."

Other inferences and theories conveying the same idea could be cited. To such an extent has the tuberculous nature of pleuritis, especially those with serous effusion, been accepted by the medical profession, that it is necessary to review the subject and determine, if we can, if this opinion is founded on facts or is an inference only.

Deductions based on clinical records and observations being always open to varied interpretations, "a trustworthy estimate of the incidence of tuberculous pleurisy can be had only by anatomical investigation." Osler² reports the results of post-mortem examination

of one hundred and one successive cases from the medical wards of the Johns Hopkins Hospital, in which pleurisy, whether fibrinous, sero-fibrinous, hemorrhagic, or purulent, was found. This series is especially valuable as the cases were not selected. Thirty-two only were tuberculous, *i.e.*, those in which tubercles were present on the pleural layers, either as fresh miliary granulations, caseous masses, or diffuse fibro-tuberculous membranes. Of these there were 8 with purulent exudate, all associated with pneumothorax; 2 with hemorrhagic fluid; 7 were cases of acute miliary tuberculosis with fibrinous and sero-fibrinous exudate; 4 were instances of acute miliary tuberculosis with purely fibrinous exudate; 13 were cases of chronic sero-fibrinous exudate with more or less thickening of the pleuræ. There were 13 cases of pulmonary tuberculosis, in which pleurisy was present without it being possible to say definitely that it was of tuberculous nature. In 10 of these the exudate was fibrinous and in 3 sero-fibrinous.

Going over the reports of the pathological findings at necropsies in different hospitals, one is impressed with the frequency of pleuritic adhesions, either local or general, unattended by tuberculosis of the pulmonary tissue or of any of the contiguous organs.

Loomis reports the result of 763 autopsies held at Bellevue Hospital, which showed 276, or thirty-six per cent., with the lungs bound down to the chest wall by organized adhesion, either general or local, in which cases the lungs were free from disease other than the pleuritic changes.

Figures have been gradually accumulating as to the proportion of cases, especially of pleurisy with effusion, in which, after recovery from the immediate effects of the pleurisy, the patient either became tuberculous or remained free from any trace of the disease. As these statistics are most instructive, I shall refer to them briefly.

Bourdisson reports 150 cases, of which only 3 developed phthisis. Coriveaud reports 27 cases followed from twenty-five to eight years without any secondary tuberculosis. Austin Flint reports 47 cases, 4 of which died of phthisis. In one only could the pulmonary tuberculosis be considered as a sequel of the pleurisy. Blackiston reports 53 cases, and in not a single instance did tuberculosis develop during several years after recovery.

Bowditch,¹ in a most valuable paper, reviewed the cases that occurred in his father's practice from 1849 to 1879—90 cases. Inquiry (1889) showed that thirty-eight per cent. only had died of pulmonary tuberculosis.

Barr² cites 114 cases occurring in children during the years 1880-1884. Of these, 74 were of simple pleurisy with effusion, and 40 were of empyema. Inquiry in 1889 showed that of the cases of simple pleurisy with effusion 17 could not be traced, 25 were living, and 32 were dead. Twenty-one, or twenty-eight per cent., had died of tuberculosis in some form. Of the 40 cases of empyema 32 were alive and healthy, 6 were dead, and 2 could not be traced.

The result of post-mortem examinations and the statistics just considered make it appear that either primary tuberculosis of the pleura is not so common as we have been led to believe, or that recovery from tuberculosis of the pleura is very much more frequent than from pulmonary tuberculosis.

Formerly the situation of the pleurisy was supposed to establish the diagnosis, but more recent investigations demonstrate that a tuberculous process may involve primarily any portion of the visceral pleura, and may express itself in an adhesive, fibrinous, serous, or purulent type, or in an acute, subacute, or chronic form.

The bacteriological examination of exudations in acute pleuritis has not aided materially in clearing up the question of etiology. In cases which from other symptoms were known to be due to pulmonary tuberculosis, the serous exudate was sterile. Prince Ludwig Ferdinand, of Bavaria, states that the tubercle bacillus has been found in the pleural exudate in only thirty-two cases. The explanation of the sterility of the exudate is, I believe, to be found in the relation that the pleural cavity bears to the pulmonary lymphatics. In Dr. Coakley's experiments, and also in coal-miners' lungs, the carbon particles are found in the lymph spaces under the visceral pleura, and none in the pleural sac. We can easily conceive that the lodgment of tubercle bacilli, or of any germ or irritant matter, could set up inflammatory changes in the subpleural tissue, which by extension would be sufficient to induce an acute pleurisy, without the specific germ that had caused the primary process invading the pleural cavity. The statement is made that when a pleuritic effusion is sterile the presumption is that it is tuberculous. I do not see why the absence of micro-organisms in the pleural exudate should be an indication of a tuberculous process any more than in the peritoneum, pericardium, tunica vaginalis, or the synovia. Granting that tuberculosis is a frequent cause of primary pleurisy, the conclusion that must be drawn from the statistics above cited, and the result of anatomical investigation, is that there is a large percentage that is non-tuberculous. Since neither bacteriological examination of the exudate and sputum, nor physical examination of the lungs, has given an adequate explanation of the acute pleuritis that were formerly ascribed to cold (*pleuritis a frigore*), the tendency has been to deny their existence as a separate type, and to include them among tuberculous cases. Many investigators who have studied these cases of acute, non-tuberculous pleurisy from the bacteriological side, claim that the majority are due to the pneumococcus of Fraenkel. Jakowski studied fifty-two cases and found that seventy per cent. were caused by the pneumococcus, while out of Netter's forty-six cases, forty were due to the same organism. Many cases of pleurisy coming on suddenly after exposure, which may or may not be ushered in with a chill and with high temperature and abundant plastic exudation, run their course without medical interference in from five to seven days, when the temperature falls, as in the crisis of pneumonia; but during their entire course there are none of the physical signs of lobar or lobular pneumonia. I think it must be conceded that it is possible to have the pleura invaded by the pneumococcus without any lung involvement. The avenues of infection are still in doubt. Some claim that the tonsils are the port of entry, and that there is general constitutional infection, with localization in the pleura.

It was not my purpose to-night to consider in any way the question of empyema, still I cannot refrain from calling attention to one point in empyema due to the pneumococcus. All admit the tendency to recovery and the rapidity and the completeness of the cure after opening the chest. I do not think that the presence of leucocytes or pus cells in the exudate of pleuritis due to the pneumococcus has the same significance as when dependent on the streptococcus or other pus-producing germs. In pneumococcus infection the most marked effect on the blood is not the increase of the fibrin factors, but the multiplication of the white blood corpuscles, or leucocytes. When the pneumonic process involves the lung, the exudation consists of fibrin and white blood cells which are not stamped with an inherent tendency to organize, for after the crisis and convalescence the lung returns to its normal condition.

Guerin has defined inflammation of serous mem-

branes as an exaggerated invasion of the lymph territory by the elements of the blood which during an attack of general infection by the pneumococcus of Fraenkel is rich in white blood corpuscles, and as the infecting agent easily loses its virulence the secondary inflammatory changes in the pleura are not induced, as in other forms of empyema.

All writers, when giving a list of the etiological factors of pleurisy, include rheumatism, but very few consider it a notable cause. I have been surprised, when investigating the etiology of my cases of acute pleurisy, at the frequency of well-marked rheumatic symptoms that preceded, accompanied, or followed the onset of the pleurisy. The forms of pleurisy were varied. Out of a total of 18 cases that could be considered rheumatic, 10 ran the course of simple fibrinous pleurisy, without any serous effusion; 3 began with fibrinous, but soon had serous effusion; and in the remaining 5 cases serous effusion was found at the time of the first examination. In 4 cases, thickening with adhesions occurred. The exudate was examined bacteriologically in the 8 cases with effusion, and no micro-organisms were found. Repeated examinations of the sputum, during and after the attack (in 9 of them over a period of more than three years) failed to show any tubercle bacilli.

The infectious matter of rheumatism (I think we are all willing to admit that rheumatism is an infectious disease), as soon as it enters the circulation, causes certain general disturbances of the organism and then localizes itself in the serous type of membranes; and while causing most frequently rheumatic polyarthritis, still it may primarily involve the most varied organs. We know that frequently the most intense cases of articular rheumatism run their course without any involvement of the endocardium or pericardium, while, on the contrary, slight attacks of articular rheumatism scarcely worthy of the name, so slight indeed as to be overlooked, or in children to be designated as "growing pains," cause the severest complication of the serous membranes of the heart; and when these cardiac conditions are found we unhesitatingly refer them to the rheumatic infection, even though the history be insufficient. When treating a case of acute rheumatic polyarthritis the physician examines daily the condition of the pericardium and endocardium, and notes any evidence of inflammation, so that the relation between the arthritic manifestation and the cardiac complication is well understood. On account of the inability of the patient in a severe attack of rheumatism to move sufficiently to permit thorough physical examination of the lungs, many cases of involvement of the pleura are not detected. When a joint has once been affected by rheumatic inflammation, it is ever afterward liable to become inflamed by very slight disturbance of the organism by the rheumatic poison. After rheumatic pleurisy the same liability to recurrence exists, usually as a mild or sub-acute process, attended by fine, crackling râles and dragging pain; although at times there is abundant serous effusion. I am thoroughly convinced that many of the cases that show at autopsy pleuritic adhesions, without any evidence of tubercle in the pleura or lung, are rheumatic in their nature, even though we admit the curability of tuberculosis of the pleura and entire disappearance of the tubercle.

Epidemics of pleurisy have been noted so frequently that the peculiar infectious agents of these outbreaks must be included in the etiology. It is only necessary to mention that infectious diseases—scarlet fever, measles, small-pox, typhoid fever, gonorrhœa, syphilis, surgical and puerperal pyæmia—may be complicated by pleurisy and that it may be a terminal process in cardiac and kidney disease.

Coincident with the general acceptance of the the-

ory that the majority of cases of acute pleurisy were due to tuberculosis came the "do-nothing" plan of treatment during the acute stage, which to a certain degree has lasted to the present. While this may be instructive to the physicians who desire to study the course of disease, undisturbed by therapeutics, still it is neither pleasant nor satisfactory from the patient's standpoint.

I cannot offer you any new treatment to-night, but will merely state the means that have given me the best results and which, in a personal experience with an attack of pleurisy, gave the most relief.

The patient should have absolute rest; this not only includes being placed in bed, but all efforts at conversation should be forbidden. As the irritating and persistent cough is one of the most annoying symptoms, this should be allayed. The ordinary sedative cough mixtures are of no avail; the only adequate means is a full dose of opium, preferably a hypodermic injection of morphine. The action of opium is not restricted to allaying the cough only, but through its action on the calibre of the blood-vessels it controls the inflammatory congestion and the subsequent œdema or exudation into the pleural sac. To control the movements of the chest, various bandages, strappings, and dressings have been devised; a broad strip of rubber adhesive plaster, or even a wide belt of leather or webbing, tightly drawn, is usually sufficient for the purpose.

As the first seat of the exudation is on the costal side of the pleura, showing that the blood-vessels of the thoracic walls take an active part in the acute and exudative stages, counterirritation by directing the blood to the surface is indicated. In the acute stage these measures should be mild, just sufficient to accomplish the purpose without causing secondary effects that would increase the primary congestion. Dry-cups, applied over the side affected, meet the requirements. They should not be left so long, nor should the exhaustion of air be so great, as to rupture the capillaries of the skin and produce ecchymoses. After cupping, if further counterirritation is desired, a turpentine stupe may be applied, or if the cupping has been sufficient poultices or warm applications should be used.

To control the fever, antipyrin, antifebrin, and phenacetin may be used. These have a twofold action—they control the pain and reduce the temperature, while some claim they have another and specific action.

Before the advent of the coal-tar derivatives aconite and veratrum viride were used to control the fever and its accompanying circulatory disturbances. It seems to me we have neglected these remedies in our eagerness to try the latest productions of synthetic chemistry. In many cases, and especially in children, they exert a far greater and persistent controlling influence over the disturbed organism than do antipyrin, antifebrin, or phenacetin. I usually begin with five or ten drops, and continue with one or two drops every half-hour until its effect on the pulse is obtained. In treating children the dose should be correspondingly small.

The giving of small doses, frequently repeated after the initial full one, is, I believe, necessary to obtain good results.

The diet should be simple, preferably milk, and a brisk saline or mercurial purge given.

The scope of the treatment of the acute stage is to control its intensity, limit the pouring out of the elements of the blood into the pleural sac, and prevent the proliferation into the subpleural tissue of cells that may organize and cause crippling of the lung by adhesions.

Although many cases of acute pleurisy stop at the

dry or plastic stage, we must regard more or less effusion as a natural part of acute inflammation of serous membranes. The primary effect of the effusion is not an untoward one, as it separates the inflamed surfaces, diminishes the movements of the pleura, and decreases lung traction. In a word, it acts as a splint to the affected side. "Fluid effusion being both natural and salutary in acute pleurisy, we must be watchful but not meddlesome in our treatment of its earlier stages; up to the end of a week or ten days we need not in ordinary cases seriously consider how to promote its removal" (Powell). During the three or four weeks following the stage of effusion spontaneous absorption can be expected. If, however, during these weeks there is a tendency for the fluid to increase, or if at any time the amount or the rapidity of the effusion causes marked dyspnoea or circulatory disturbance, active measures are to be used.

During the weeks that we may expect spontaneous absorption, what should be our plan of treatment?

With the subsidence of the pain that occurs with the onset of the effusion, opium should be stopped. The patient should be kept in bed until four or five days after the occurrence of any pyrexia, when he should be allowed to get up. His diet should be simple and no active medication used, except that necessary to restore the functions of the organs deranged by the fever.

As we noted when treating of the physiology of serous membranes, the normal exchange of fluid in the pleura is favored by the movements of the chest in breathing. One of the prominent symptoms of effusion is loss of motion of the affected side, and one of the most encouraging signs of absorption is the return of the contractions of the intercostal muscles. To simulate these normal forces we may employ compression of the thorax during expiration for five or ten minutes twice a day, and when tenderness has disappeared massage of the intercostal spaces.

Of the medicinal substances that have been used to hasten absorption, by acting on the elements of the effusion, mercury and the iodides have had the greatest reputation.

Aufrecht first called attention to the use of the salicylate of sodium in causing absorption of inflammatory effusion from serous cavities. Since then Tetz, Wenci, Germain Sée, Devi, and others have advocated its use.

Stritzover gave fifteen grains three times a day, and guarded against any depressant effect by the simultaneous administration of stimulants. He treated eight cases. Seven recovered in eighteen days; one case did not show any improvement on the fourth day, when aspiration showed that the effusion was purulent. He holds it a most valuable remedy in serous effusions, and at the same time a means for differentiating serous from purulent forms.

Koster claims that in his cases absorption began at once and a large effusion began to lessen in five days.

Dr. Zewiecki claimed that: (1) Inflammation of the pleura, on which no other remedies had any influence, subsided quickly under salicylate of sodium; (2) the use of the salicylate of sodium internally produced after twenty-four hours a favorable turn in the course of the disease; (3) the temperature fell; (4) the quantity of urine rose and with it the quantity of the chlorides, accompanied by diminution of the pleuritic effusion. This treatment was continued two weeks, after which time the patients regained their health.

To obtain these results it was necessary to give at least two drachms a day, in the following manner: twelve grains every hour until the toxic physiological effects—buzzing in the ears—appeared, and then the same amount every two hours. To avoid gastric irrita-

tion, he advised its administration in milk. In a later paper he said salol had the same action, without any of the unpleasant effect of the salicylate of sodium.

Various theories have been advanced to explain the action of the salicylates in causing absorption of the effusion. Steller claims it is due to diuretic action, while Eichhorst says it depends on sudorific action. Talamon claims for it a specific action, based on the experiments of Rosenbach and Pohl, who found that when salicylates were introduced into the digestive tract, they were found later in all the healthy serous cavities of the body, as well as in those that are of a morbid condition.

To hasten the absorption into the blood-vessels, diminution of the watery elements of the blood by diuresis and catharsis has been used. Dependent on the same principle is the treatment by "dry diet." This consists in withdrawing all liquids for three or four days, compelling the blood-vessels to slake their thirst from the well of the affected pleura.

Few patients are willing to endure the annoying features of this plan. A modification is to gradually reduce the quantity of liquid exhibited, taking as the guide the amount of urine voided. Each successive day the quantity of liquid given is smaller than the amount of urine passed. All these plans of treatment have succeeded and likewise have failed in diminishing the amount of the effusion. The longer the fluid remains stationary in the pleural cavity, the greater is the tendency for coagulation of the fibrin-factors to take place on the surface of the pleura, and thus seal the opening of the lymphatics; when the pleurisy has been attended with marked inflammatory changes in the subpleural tissue, the lymph channels are closed and absorption is impossible. When these conditions exist it is necessary to remove the fluid by thoracentesis or incision.

The advisability of removal of the effusion by thoracentesis when there is advanced tuberculosis of the lungs demands consideration. One of the reasons why pulmonary tuberculosis is so resistant to treatment is the never ceasing activity of the lung. We can immobilize a tuberculous joint, but have devised no apparatus to accomplish this for the lung.

Fluid effusion into the pleura, by allowing the lung to retract and stopping all motion of the affected side, gives the needed rest, and permits those changes to take place which tend to arrest the advance of the tuberculous process. I have frequently seen aspiration of the fluid followed by rapid extension of the disease, and in four cases by general tuberculosis.

What the fluid does for the protection of a whole lung, localized pleuritic adhesion does for the part bound down. All who have seen much of pulmonary tuberculosis have noted how the occurrence of a localized adhesive pleurisy has been followed by a more chronic course and even arrest in the pulmonary process. I am more and more impressed that pleurisy in pulmonary tuberculosis is a conservative process. Nature is frequently prodigal in her attempts to combat morbid processes, and the secondary pleuritic adhesions tax our diagnostic resources and therapeutic judgment to the utmost to decide on a safe plan of treatment. I believe harm frequently follows the forcible distention of the lungs and the breaking up of these adhesions.

Conclusions.—(I.) It is impossible for records or observations from any one source to settle the question of the proportion of tuberculous and non-tuberculous pleurisies. Different observers will arrive at various results, according to the character of the infectious material most prevalent in their localities. Figures will also be influenced by the occurrence of epidemics, and the surroundings and social status of the subjects observed.

(II.) That in pulmonary tuberculosis an intercurrent attack of pleurisy may be non-tuberculous.

(III.) That frequently an attack of acute pleurisy is the first intimation of a pre-existing or latent pulmonary tuberculosis.

(IV.) Since neither the onset of the pleurisy nor the character of the exudation presents any diagnostic etiological features, careful and repeated examinations should be made of the sputum for the tubercle bacilli.

(V.) As it is generally impossible at the onset to say what is the nature of an attack of pleurisy, and even if it is considered non-tuberculous, we should recognize the fact that the barriers which nature has placed against the introduction of infectious matter into the respiratory tract have been broken through or removed, and until these have been replaced and the normal resistance of the organism restored, it is necessary to guard the patient against all sources of infection.

A RATIONAL TREATMENT FOR PHTHISIS PULMONALIS, TOGETHER WITH SOME NOTES ON A NEW REMEDIAL SOLUTION.

By CYRUS EDSON, M.D.,

NEW YORK.

DURING a study of phenol, made in the early part of 1895, I was very much struck by the observations of Stadler, Merck, Brieger, Salkowski, and others. These investigators declared phenol could be found in the urine of man, the horse, and the cow.¹

According to Merck, healthy urine from a mixed diet contains 0.004 gram of phenol per litre, and, according to Salkowski, under pathological conditions the amount may rise as high as 1.5575 grams; in other words, during health phenol is a normal constituent of the urine,² and during disease the per cent. present is enormously increased.³

It has long been my personal belief that many pathological phenomena observed in diseases which are not usually credited to germ infection, are but the manifestations of the absorption of poisonous bacterial products. For example, the high temperature of fever may arise from the poisoning of the nerve-centres by such products. If this be true, then the increased secretion of phenol by the system during disease is, in fact, one of Nature's many devices to cure the underlying condition, to destroy the germ infection. The increase of phenol elaborated by the system during pathological conditions is, in the light of the knowledge we have of bacteriology and of phenol, extremely significant. This reasoning naturally led me to think phenol was selected by Nature for the cure of some, at least, if not all, of the so-called germ diseases. Of course, the conclusion was obvious, but the corollary of that conclusion, which assumed great importance in my mind, was this: If Nature herself provides phenol during disease, then it cannot be possible she will not tolerate the administration of the agent in effective dosage. Yet this fact stared me in the face, that an injection of any known solution of phenol in

¹ Am. Chem. Pharm., lxxvii., 360.

² Phenol occurs in the urine as the potassium salt of the unstable phenyl-sulphuric acid, and for this reason can be detected only by distillation with hydrochloric acid (see Ber. Deutsch. Chem. Ges., ix., 1505-1506). According to Brieger, phenol is also found in small quantities in excrement (Jour. Prakt. Chem. (2), xvii., 133).

³ Brieger found increase of phenol in urine during scarlatina, erysipelas, etc. (Hoppe-Seyler's Zeitschr., iv., 204). According to Wohler the præputial glands in the beaver secrete a substance known as castoreum which is found to contain small quantities of phenol (see Am. Chem. Pharm., cxvii., 360). It has also been demonstrated by Baumann that when albuminoid bodies are allowed to putrefy in the presence of some water and pancreas phenol is formed (Ber. Deutsch. Chem. Ges., x., 685).

effective dosage was believed to cause poisonous symptoms. This was equivalent to saying there must be some form in which phenol could be injected in effective dosage, which would aid Nature in her efforts to effect a cure, and which would be tolerated by the human system. Moreover, it was apparent to me that phenol, being the only known antiseptic agent, except its homologue, cresol,¹ of which the amount in the system is increased during disease, it would be the best to select for experimental purposes to the exclusion of any other. When we follow Nature along her efforts to effect cure, we cannot go far wrong. The problem before me, then, was to find the form of solution of phenol which Nature would tolerate.

With this idea in mind, and remembering the fact that creosote has been, and is, extensively used for the treatment of tuberculous disease, more especially for pulmonary tuberculosis, and, furthermore, knowing that creosote, according to the latest chemical researches, is not phenol,² as it was formerly supposed, but merely has the latter as one of its constituents, I formed the opinion that the so-called creosote treatment, which may almost be said to have become a fad among physicians, depended for its success mainly on the presence of the phenol the creosote contained.

Now, there is a fatal objection to the creosote treatment, namely, its derangement of the digestive function when continued for any considerable length of time, and this objection holds equally good in the case of phenol administered by the mouth. Therefore, it was apparent that some other mode of administration should be chosen. I then took into consideration Gilbert's reports³ of the administration of phenol solutions by the rectum in cases of phthisis, and came to the conclusion that the favorable percentage of cures (Gilbert claimed twenty-five per cent.) would probably be very much increased if the phenol could be administered hypodermatically. This I found had been done by Declat,⁴ Sistini, and others,⁵ who had made steps in advance of the former observer. The preparations of phenol recommended by them did not give me results with which I was satisfied.

I determined, therefore, to experiment with a view of producing a fluid which could be administered hypodermatically, without irritation or toxic effects, and which should at least contain phenol in such effective dosage as would turn the scale of natural resistance in favor of cure. I am well aware that many men have drawn conclusions from experimental research that at least one per cent. of phenol to the entire amount of blood in the system is necessary to effect the result I aimed at, and that such an amount would be overwhelmingly toxic.⁶ But these scientists too often lose sight of the fact that experiments outside of the body are not, and

never can be, identical with results depending in part on factors operating within the body. The blood is an antiseptic fluid when within the body, and one of very considerable power. Its natural resistance to germ infection, though this doubtless varies in different individuals, is great. A comparatively small amount of antiseptic reinforcement, therefore, may be sufficient to increase that resistance to the desired point.

I will not enter into a description of the long line of experimental work in the laboratory which finally led to the production of the fluid I have used in my formulated treatment of phthisis.

In order to enable physicians who have used it to understand what they were administering to their patients, I prepared a confidential circular, which contained an exceedingly rough description of the method of manufacture. It will at once be apparent, from the report printed below, that it would have been impracticable for me to send a detailed description, such as is here given.

Desiring to have the description of its manufacture as complete and scientific as possible, I requested Professor Henry A. Mott, the distinguished chemist, to investigate the process and report to me. Dr. Mott kindly consented, and his report is as follows:

"LABORATORY OF HENRY A. MOTT, PH.D., LL.D.

"Cyrus Edson, M.D.

"DEAR SIR: Pursuant to request, I have examined the preparation known as 'aseptolin,' as also the process employed in its manufacture, and I have the honor to report as follows:

"By means of chemical analysis, there can be separated from the fluid in question a colorless crystalline salt, which is new to the medical profession, being a chemical combination of absolutely pure phenol (C_6H_5OH) and the alkaloid pilocarpine ($C_8H_9N_2O_2$). This pilocarpine-phenyl-hydroxide ($C_{11}H_{16}N_2O_2.OH.C_6H_5$) exists in the fluid, dissolved in an aqueous 2.75 per cent. solution of phenol.

"The Composition of the Fluid.—

	Per Cent.
Water (H_2O).....	97.2411
Phenol (C_6H_5O).....	2.7491
Pilocarpine-phenyl-hydroxide ($C_{11}H_{16}N_2O_2.OH.C_6H_5$).....	0.0188
Total	100.

"The composition of pilocarpine-phenyl-hydroxide ($C_{11}H_{16}N_2O_2.OH.C_6H_5$), deduced by calculation, is as follows:

	Per Cent.
Pilocarpine ($C_{11}H_{16}N_2O_2$)	53.92
Phenol (C_6H_5O).....	46.08
Total	100

"It is not the function of the chemist to speak of the medicinal properties or applicability of a drug, hence I will proceed to a description of the manufacture of the new compound which you have, after laborious research and experiment, produced, and also set forth the process adopted for the production of aseptolin.

"Your experiments have shown that none but the very purest chemicals can be employed. The phenol obtainable in the market, besides containing traces of para-cresol (C_6H_4OH), contains, as a rule, other impurities which unfit it for the direct preparation of this fluid.

"Starting with phenol distilled directly from its hydrate ($2C_6H_5.OH_2O$), which has a much higher melting-point and a much lower boiling-point than the phenol ordinarily obtainable, I find that you subject a solution of such phenol, distilled in water, to an additional distillation, heating the vapor as it passes from the retort to the receiver in an oil-jacketed tube

¹ Cresol hydrate is the homologue of phenyl hydrate and we might expect to find cresol (tauric acid) in the urine, in fact Baumann found it in the urine of graminivora, occurring as the potassium salt of paracresyl-sulphuric acid (Ber. Deutsch. Chem. Ges., ix., 1, 359, 1, 716). Urine of the horse also contains some orthocresyl-sulphuric acid according to Preusse (Hoppe-Seyler's Zeitschr., ii., 355, also Ber. Deutsch. Chem. Ges., xi., 1911).

² While creosote has under certain favorable circumstances proved of value, still it cannot be relied upon. This fact is readily explainable, as Hugo Miller, Gonup-Besanez, Marasse, and Tiesnan have shown that creosote is not phenol, but that, although it contains some, it is composed principally of paracresol, phlorol, guaiacol, cresol, methyl-guaiacol, methyl-cresol, etc., all of which exercise certain actions on the system peculiar to themselves. Creosote contains: Some phenol, C_6H_5OH ; paracresol, C_7H_7OH ; phlorol, C_8H_9OH ; guaiacol, $C_8H_7OCH_3.OH$; cresol, $C_7H_7OCH_3.OH$; methyl-guaiacol, $C_8H_9OCH_3.OCH_3$; methyl-cresol, $C_8H_9OCH_3$ (OCH_3)₂, etc.

(in which a thermometer can be inserted), and then condensing the same in a double-stoppered receiver, which enables you to reject the first ten per cent. so condensed, utilizing the remainder, with the exception of the last ten per cent., which is likewise rejected.

"In the preparation of pilocarpine-phenyl-hydroxide, it is necessary only to weigh out an equivalent proportion of this purified phenol solution (after determining its strength by chemical analysis), heat the same to about 100° C. (212° F.), and then gradually add to it an equivalent amount of the pure alkaloid pilocarpine, when, on standing for ten or twelve hours, the uncrystallized pilocarpine-phenyl-hydroxide will separate out. From this salt the fluid may be directly prepared, by following the analysis given above. The usual method, however, adopted in its preparation on an extensive scale is as follows:

"The highly purified phenol is diluted with distilled water until the percentage of phenol is reduced to exactly 2.75 per cent., which can be determined by the phenolometer. This is introduced into glass-stoppered receivers, which have been thoroughly cleansed with boiling water. In the receiver the right proportion of the alkaloid pilocarpine is put, so that, as the phenol distills over and condenses, it immediately combines with the pilocarpine in the production of the fluid. The temperature of the receiver is kept reduced by means of a small stream of water, yet sufficiently high to insure the desired union, but is never allowed to approach a temperature which would permit of the alkaloid suffering any other chemical change.

"Experiment has demonstrated that strict adherence to the above methods is required in order to produce aseptolin of a uniform composition and of an absolutely colorless physical appearance. A cloudy, milky, or slightly tinted preparation should be rejected. The proportions of the constituents do not permit of the presence of even traces of foreign bodies, if reliable results are to be expected. I am, sir,

"Yours respectfully,

"HENRY A. MOTT, PH.D."

It will be noticed that Dr. Mott speaks of "aseptolin." Thinking this was a good word, and following the convenient fashion of substituting a name for a formula in writing, I have called this chemically pure solution of phenol and pilocarpine-phenyl-hydroxide, aseptolin, because it is more convenient than is the repetition of the formula; but it is unnecessary for me to say that in order that such a name may not be classed with that of a proprietary remedy, the profession is free to substitute a better term if need be, and either in its present form or in any other, the new agent can be used as freely as any compound or combination of the Pharmacopœia.

Pilocarpine was added to the solution for two reasons: 1. To induce leucocytosis; 2, to stimulate glandular activity. It also accomplishes a third purpose, for it is an expectorant and stimulant of secretion of very considerable power. It causes a certain increase in the amount of water separated from the blood in the lung cells. This is shown by the fact that there is an increase of watery vapor carried off by the breath of a person taking it.

A short study of pilocarpine is interesting. A. Curci² states that this drug produces hypersecretion; in large doses it causes convulsions and paralysis. The paralysis is accounted for by regarding pilocarpine as a quaternary ammonium compound; but phenol and the

oximhydroxyl group are more powerful in producing hypersecretion, while at the same time there is less danger of causing convulsions and paralysis. It is not improbable that in the organism change may occur, a pilocarpinate being formed with the bases of the body. In dogs the drug leaves a body in the urine as free pilocarpine, and also as a pilocarpinate. Pilocarpine has been used in croup and diphtheria by Sziklai,¹ he giving pilocarpine hydrochloride in doses 0.02 to 0.07 gram for children, and 0.08 to 0.10 gram for adults. Leyden has used one-half to two per cent. solution for subcutaneous injection. Ringer and Jamison² have administered for experimental purposes 0.0325 gram of nitrate of pilocarpine. Weber³ experimented on himself, using 5 c.c. of a one-half per cent. solution. No one who has given a large dose of jaborandi or its principal alkaloid, pilocarpine, and has observed the enormous amount of water that almost fills the lung cells, the small and larger bronchi, will forget the danger that impends from œdema of the lung. Of course, the amount of pilocarpine, even in the largest doses of the fluid, is not sufficient to cause a perceptible effect in this direction.

From what has been said, it will be apparent to all chemists that the fluid is a hydrophenol, containing a definite amount of the new pilocarpine compound.

It is not very difficult to make, provided one has the apparatus and is sufficiently careful. It needs extreme care. The experience of my laboratory assistant, as written in a note to me, was as follows:

"For two months I could not produce a satisfactory fluid more than once in three times: in fact, I think we threw away, during the first three months, about one-half or nearly all of what we made. The results of our experiments with guinea-pigs were such as to convince any one that no phenol solution of the strength of the pilocarpine-phenyl-hydroxide solution, except the latter, could be safely injected. If other men make it they should be extremely careful, otherwise their product may give rise to serious consequences. At the same time there is no reason why a competent chemist should not make it successfully."

The solution prepared in my laboratory is a colorless fluid, strongly refracting light, having the characteristic odor and taste of phenol. Injected under the skin, it causes a sharp, burning pain, not so severe as that following an injection of bichloride of mercury in solution. In the great majority of cases the injection is not followed by any local irritation whatever. In a few, a small nodule appears at the point of injection, which, as a rule, disappears after a few days. Dr. Glover C. Arnold, of New York, declares that this nodule results from injecting fluids against the flow of the capillary lymphatics, and advises all hypodermatic injections to be made with needle inserted in the direction of the flow of these lymphatic vessels. This, in the abdomen, which in my opinion affords the best site to give large injections, would be effected by directing the insertion of the needle away from the median line. Though I have given over one thousand injections, and some of them very large ones, viz., single injections of three hundred and fifty minims each, I have not seen a single abscess resulting therefrom, and nodulation in only two cases; one of these was on my own person, following an injection of two hundred and fifty minims for experimental purposes. No reaction, such as follows the administration of tuberculin, is observed after the injection of properly prepared pilocarpine-phenyl-hydroxide solution, nor is there any visible physiological action noted following an injection of two hundred and fifty minims, given to a man weighing one hundred and fifty pounds, except

¹ "Beobachtungen an Leukocyten, sowie über einige therapeutische Versuche mit Pilocarpin bei der (Diphtherie?) Streptokokken-Angina, Lymphdrüsen-Erkrankungen, Tuberculose und Lupus," von Dr. Louis Waldstein aus New-York (Sonderabdruck aus der Berliner klin. Wochenschr., 1895, No. 17).

that the urine passed subsequently reacted strongly to tests made to ascertain the presence of phenol, and traces of phenol were noted in the condensed vapor of the breath, and in the contents of the stomach drawn off through the œsophageal tube within three hours of injection.

The effect of the solution when injected into the organism of a patient suffering from disease caused by active germ infection, is to directly inhibit bacterial development, and consequently to diminish the production of poisonous bacterial products. Its beneficial effects are so quick and positive, in the great majority of cases, as to convince any one who uses it of the correctness of this conclusion. Phenol and pilocarpine phenate both stimulate glandular activity, and exert a physiological effect in this direction over the range of which they act synergistically. It follows, therefore, that the remedy stimulates the production of the leucocytes.

Experience certainly has taught us that stomach derangement in cases of phthisis, if not speedily remedied, very quickly results in the death of the sufferer. It is right here that I claim an enormous advantage for the treatment that I am using. It enables us to save the stomach for alimental purposes alone, and by giving easily digested, rapidly assimilated, and highly nourishing food, a very great factor in a favorable result is secured.

The dosage, so far as I have been able to formulate it, in a case of phthisis, should begin with fifty to seventy minims daily, given in the abdominal parietes in a single injection. This dose should be increased about ten minims daily, until one hundred or one hundred and twenty minims is reached. Thus, commencing with a dose say, of seventy minims on the first day of treatment, on the second day eighty minims should be given, on the third ninety, and on the fourth one hundred. This latter dose should be kept up daily until the patient has recovered, or until some symptoms appear which indicate to the attending physician the discontinuance of the fluid. This would probably be the case if, for instance, albumin should appear in the urine, or if unusual nervous symptoms should develop, or if persisting nausea should be present, or if any symptom which was evidence of a personal idiosyncrasy against the remedy should show itself.

With these injections—I inject daily, or in some cases every other day, the treatment depending on the severity of the disease and the response of the patient to the remedy—I give inhalations delivered from a Sass spray tube and a globe inhaler. These inhalations are of very great importance. The most efficient of the sprays I have found in a ten-per-cent. solution of iodoform in ether:

Iodoform	10 parts.
Ether.....	90 "
	100 parts.

This is given once or twice daily through a Sass tube having laryngeal delivery. The spray is best given under a delivery pressure of one atmosphere. This, of course, necessitates the use of an air pump and a receiver, which can be purchased from almost any reputable surgical instrument-maker. The spray tube should be introduced in such a manner that the tip nearly touches the posterior pharyngeal wall, when the spray will be delivered into the larynx. Care should be taken not to deliver the spray too forcibly. The patient should inhale and exhale deeply during the delivery of the spray, in order to draw the spray as far into the affected region as possible.

The object of the spray is to assist in clearing the larynx and bronchi of infective material contained in their secretions.

In some cases it will be found almost impossible to give the spray in a satisfactory manner at first. A spasmodic cough will follow the first inhalation. Experience of this kind led me to use a solution of phenol in water, containing some glycerin to assist nebulization. Expressed in form of a prescription, this would be as follows:

R Acid. carbolic	3 parts.
Glycerini	10 "
Aquæ destil	87 "
M. Sig. Use in globe or other inhaler.	

After a few inhalations of this, the air passages, as a rule, lose their irritability, and the iodoform and ether can be readily used.

A few patients will be found, however, to whom the odor of ether is intolerable. To these I give an inhalation of olive oil, containing ten per cent. of iodoform in solution. This solution can be made readily by any pharmacist. Iodoform is not very soluble in albolin, or this would afford, perhaps, a better menstruum for the purpose than does olive oil. The vaporization of the iodoformized oil is best effected by means of the globe inhaler. Lacking this, the McBride inhaler may be used, or it may be given with one of the nebulizers, such as are found in the pharmacies. I consider the oil and iodoform an efficient substitute for the iodoform and ether solution. I have seen no ill effect from the cold vapor produced by the ether solution in any case I have had under treatment, and my experience has led me to consider it the best of all inhalations for phthisis when it can be used.

I have obtained good results in the treatment of atelectasis by means of compressed air which is delivered through a large globe inhaler, at a pressure of about ten pounds to the inch. This should be used with caution, and not in advanced cases, lest it cause hemorrhage. The method of procedure is as follows:

The inhaler being connected with its atomizing attachment, the openings into the afferent end are closed, so as to permit the interior of the globe to hold the pressure when the patient's lips close over the mouth-piece. The air being turned on, the patient is directed to inhale deeply. The deep inhalation, aided by the vis a tergo of the compressed air, forcibly distends the lungs, opening up disused portions, into which the vaporized spray is carried. After practising this procedure the first few times, the amount of expectoration is frequently increased to a very great degree, and breathing becomes much freer and easier. The pneumatic cabinet would doubtless afford a more efficient means of effecting this than the one just described, but few physicians can afford to purchase so expensive an apparatus.

A number of patients present themselves who seem to have forgotten how to breathe properly. They expand the lungs so feebly that the distal parts seem to have consolidated simply from want of use. A little earnest advice on the use of "lung gymnastics" at home, together with the forcible inhalation through the globe inhaler, accomplishes much.

My experience with pilocarpine-phenyl-hydroxide in the treatment of malaria leads me to consider it a specific, and of even greater efficiency than quinine.

I have personally treated thirty-eight cases of this disease. In the great majority of cases the mode of administration was as follows:

On the first day of treatment, two hundred minims were injected as an initial dose. This was delivered into the abdominal parietes in two injections of one hundred minims each, on either side of the median line, the point of the needle being directed away from it. On the second day and each day following, until and including the seventh day of treatment, one hundred minims were given (injected into the ab-

dominal parietes in different places, first on one side of the median line, and then on the other). Then, on three alternate days, one hundred minims were given in a like manner. On the twenty-first day a dose of one hundred minims was administered, and, finally, the treatment was concluded with an injection of one hundred minims on the twenty-eighth day. Latterly I have given two hundred minims on the twenty-eighth day as a final dose.

In not a single case has there been any recurrence of the malarial paroxysm after the first injection of two hundred minims, nor have any of my cases had a recrudescence or a recurrence of the attack. The patients appear well in every way within a few hours of the first injection. The medicine appears to act equally well when given during the paroxysm, or during the intermission or remission, and in remittent types as well as intermittent. Dr. John H. Ripley, of New York City, used the solution in two cases of malaria, which he describes as follows:

"The first was a complicated one, but the malarial factor seemed to yield readily. The second was a very chronic malarial poisoning, in a very young girl. Her case was treated according to your plan, carried out to the letter (described in the foregoing). She came from Brooklyn, and remained in New York so as to get the full benefit of the treatment. The disease yielded by degrees. After one week she appeared well, but a relapse occurred a week after the treatment was discontinued. I then sent her to a non-malarious country place in Connecticut, where she has since resided, and remained well. This was a very obstinate case of recurring malaria, in which I had given large doses of quinine hypodermatically, with only temporary relief."

In reporting results obtained from the application of the treatment described in the foregoing, I find myself confronted by many serious difficulties, not the least of which are lack of time and space. My practice has demanded an amount of attention that has put serious obstacles in the way of my work. I have, however, been very greatly assisted in testing the fluid by able practitioners, to whom I owe a debt of gratitude. Among these are Dr. R. P. Lincoln, Dr. John G. Perry, Dr. E. N. Brandt, Dr. John H. Ripley, of New York City, and Dr. Lewis Balch, of Albany, N. Y. The experience of these gentlemen will probably be given in articles of their own. I have prepared and written reports of a large number of cases treated, but in an article of this kind find space for only a very few typical ones, more to illustrate the method of treatment than its efficiency.

CASE I.—W. M.—, male, aged twenty-four, good family history. Has suffered from cough; normal weight, about 158 pounds; September 3, 1895, 128 pounds; had occasional night sweats and attacks of facial and intercostal neuralgia. Expectored about an ounce and a half of muco-purulent sputa daily, containing large numbers of tubercle bacilli, also streptococci; a slight daily rise of temperature, 99.4° F. to 100.3° F. being the evening temperature. Physical signs showed a small cavity surrounded by an area of consolidation, in middle lobe of right lung. This general condition was first noted in December, 1894, but improved so as to have entirely disappeared during a six months' residence in New Mexico. Upon return to New York, there was recrudescence. Prior to September 3d he received extract of malt with cod-liver oil, creosote carbonate, and a cough mixture containing codeine and ammonia. Under this the patient rapidly lost ground.

September 3d.—Sixty minims of the fluid were injected into the abdominal parietes, and iodoform spray administered. Nutrient treatment, consisting of emulsion of cod-liver oil, somotose in chocolate,

egg phosphate, etc., was prescribed. The dose of the fluid was increased ten minims daily, until one hundred minims daily were given.

September 10th.—Cough much better, expectoration diminished one-half, and containing fewer bacilli; temperature normal; no return of night sweats; physical signs seemed slightly improved.

October 1st.—Had had one hundred minims daily since September 10th, and the spray had also been daily administered. No cough or expectoration; with difficulty a little sputa, consisting purely of mucus, could be obtained, and this contained no tubercle bacilli. The patient seemed in normal health; had gained six pounds; appetite excellent; objected to further treatment, on the ground that he was well. This improvement has been held until the present time, January 4, 1896, except that the patient had a severe coryza and slight bronchitis in November, which necessitated treatment for one week, during which he was given one hundred minims of the fluid daily, and the spray as described in foregoing. Patient has not yet regained his normal weight, however, weighing at date 148 pounds. His sputa have been repeatedly examined, but no bacilli have been found.

CASE II.—L. B.—, female, twenty-two years of age, married, good family history, has had two children, both being well and strong. Disease is of long standing, beginning some time in 1892. Apices of both lungs showed extensive atelectasis; bronchitis with profuse expectoration, about three ounces of muco-purulent sputa daily; no cavities, but some shreds of fibrous lung tissue in sputa, which also contained large numbers of tubercle bacilli; loss of weight, strength, and appetite; diarrhoea; night sweats; cough severe and almost constant, breathing hurried; shortness of breath preventing much outdoor exercise, very little exertion inducing palpitation; patient very anæmic. An ulcer, probably tuberculous, was disclosed by laryngoscopic examination in arytenoid space. Patient spent the summer at Liberty, N. Y., and had greatly improved, but lost this improvement, and something more, on return. A treatment up to October 17th had consisted solely of creosote, cod-liver oil, and quinine. On October 17th, one hundred minims of the fluid and the spray of iodoform and ether were administered, and these were continued daily thereafter until October 20th. No change, except that patient said her appetite had much improved; she also said something was making her nervous; the bowels were still loose. One hundred and ten minims of the fluid and spray were daily administered, until November 1st. Within this period a very great change for the better had taken place; patient coughed less, slept well, had good appetite, had gained three pounds in weight, expectoration was much less, and there were no night sweats. Tubercle bacilli were still present in the sputa, but in less numbers, and no lung tissue appeared under the microscope. The movements from the bowels had been normal since October 22d.

This patient's daily condition continued to improve until November 28th, under the daily treatment I have described. Just prior to this date her sputa were examined, and no tubercle bacilli found. She had gained ten pounds in weight, and the amount of sputa decreased until only about one-half ounce daily was expectorated; her cough grew less and less. On the latter date (November 28th) the patient complained of nausea and loss of appetite. These conditions persisted for a week without return of other symptoms, except that the patient lost about three pounds in weight. Feeling that the treatment was causing the unfavorable symptoms, I discontinued it for one week, during which they ceased. During the discontinuance of the treatment she developed an attack of acute bronchitis,

and while she was still suffering from it I resumed the treatment, giving one hundred and twenty minims the first day and the spray. The following day I gave one hundred minims and spray, and continued that treatment daily for one week, then every other day until the present time (January 4, 1896). She recovered quickly from the bronchitis, regained her weight and about six pounds additional. Microscopic examination shows a recrudescence of the tuberculous infection. She still has a slight cough; the laryngeal conditions disappeared during the fourth week of treatment. She expectorates at present but very little, and the sputum still contains a few tubercle bacilli. There are no night sweats. Patient is strong and able to take an abundance of outdoor exercise.

This case is a very good example of a number in my own practice and in that of other observers, where the treatment has accomplished a great deal, and where it promises still more. At the same time it is a constant struggle in these cases to keep the upper hand of the disease.

The reports which follow I have received from Dr. John G. Perry, of New York City. Dr. Perry's practice makes such demands on his time that he found it impossible to write more fully. As he says in the note which came with the reports:

"If the enclosed cases are of any value to you, pray use them. I have had to write them as they appear, for I had no more time to give. Really, one needs more time than I have been able to find, to properly study the results of your solution of pilocarpine-phenylhydroxide.

"CASE I.—Miss C——, family history good. Had suffered for several years from insufficient sleep, hemi-crania, cold extremities, dysmenorrhœa, and menorrhagia. Very anæmic. Not finding uterine disease or displacement, and learning that she had formerly resided at Elizabeth, N. J., concluded that the condition was one of miasmatic origin, and began the use of hypodermatic injections of pilocarpine-phenol (Edson), without adjuncts. As she was not able to visit me daily, there was no regularity in the treatment, but improvement began at once. Menstruation began after the fifth injection, lasted but four days, and was not attended with pain. After the tenth injection, being free of the symptoms complained of, was discharged.

"CASE II.—Miss G——, aged twenty-two years. A resident of Long Island. Had long known of her as a victim of insomnia, mental depression, and dyspepsia. In 1894 she appealed to me for relief from the above symptoms, and also from acute indigestion, which indicated gastric catarrh. For this I employed lavage, which gave her immediate relief, but exacerbations occurring whenever the atmosphere became humid, as she found it difficult to come to the city regularly for treatment, she was taught to use it herself. Recognizing the cause to be malarial and one she had never suspected, as she could not remove herself from its influence, I thought it more charitable not to mention it to her; but after receiving the pilocarpine-phenol (Edson), I sent for her and kept her in town, and gave daily injections of it in fifty-drop doses, hypodermatically. At the end of three weeks she had recovered her health entirely, could sleep through the night, was without headache and without indigestion, and had gained nine pounds in weight. She returned home, December 30th, and has remained well since.

"CASE III.—Miss T——, aged twenty-six years. Father died of cancer of the stomach. Mother a neurotic. Always delicate, of feeble constitution, and subject to bronchial cough as well as gastric catarrh. At the time of receiving the solution from Dr. Edson, she was preparing to go South, having developed a lesion at the apex of the right lung, with cough, sputa, a constant temperature of $99\frac{2}{3}$ ° F., and the beginning of a

catarrhal form of phthisis. As the patient lived far away, and could come to me only when the weather permitted, I could not carry on the treatment according to Dr. Edson's formula, but on January 9th I gave the twelfth injection of fifty minims. The cough has ceased, temperature fallen to $98\frac{3}{4}$ ° F., appetite has improved with general strength, and the patient is so much improved that she begs permission to remain at home to continue treatment.

I have used injections of the solution in a number of cases of catarrhal and febricular gripe, occurring from the first week of December, 1895, to January of this year. No bacterial examination was made in these cases, however, and I can only say that they presented symptoms which were referable, in my opinion, only to contagious influenza. Two cases will serve to illustrate its effect in this disease.

CASE I.—S. C——, aged thirty-two years, residence Elizabeth, N. J. January 15th, this gentleman called at my office, after having had a severe chill. Temperature, 103° F.; severe muscular pains, also pains in knee-joints. This gentleman has had severe attacks of gripe, and declares his disease identical with other attacks which occurred during the prevalence of gripe. I administered one hundred and eighty-seven minims of the fluid in a single dose, sent him home, where he remained in the care of Dr. McLane, of Elizabeth, who gave him one injection of one hundred and twenty minims. He was completely well after about six hours. His previous attacks, he says, were not so severe at the outset, but lasted from ten to fourteen days.

CASE II.—Mrs. T. F. G——, aged twenty-two, had slight chill, followed by extremely severe cough and fever, December 12, 1895. Subcrepitan râles were heard over posterior of both lungs; temperature, $103\frac{1}{2}$ ° F.; respiration, rapid; pulse, 120, full and bounding. Severe pains over chest from coughing; face flushed; profuse sweats; extreme depression. This patient for three days remained in about the condition I have described. On the fourth day, owing to having slept exposed to a draught, her symptoms appeared suddenly worse. Patient had a slight chill; temperature, taken after its immediate subsidence, was found to be 104° F. I gave a single dose of two hundred minims of the fluid, and this was followed by a subsidence of all symptoms; within twenty-four hours she was convalescing nicely. I did not repeat the dose of the remedy. She made an uninterrupted recovery, and was able to go out and resume her ordinary habits of life, within four days after the injection.

It is necessary to say a few words in reference to the permanence of any cure or apparent cure in a case of tuberculous disease. In the first place, patients once having had such a disease, must be considered susceptible to its infection and liable to a reinfection and a new attack. Their susceptibility, however, is likely to diminish. Each year, as they grow older, will doubtless effect changes that will render their systems less favorable soils for the growth and development of the bacilli. Second, areas of infected structures may become encysted and remain so for long periods, during which an apparent cure will seem to have taken place, the condition being one which, in fact, will delude the patient only while the encystment endures. Should something occur to break the latter down and free the bacilli, a recrudescence of the disease will at once follow. These two conditions, it seems to me, must always obtain, and must be considered not only in the case of the treatment I have just described, but as affecting the permanence of results that may be obtained through the means of any treatment that does not involve the use of a preventive virus.

Time and space have permitted only the description of the treatment with sufficient detail to enable any

physician to apply it. Beyond this—and a few references to the theory I believe underlies it—I have not gone. We pride ourselves, and justly, on this side of the Atlantic, on our practicality. As physicians, we ask for results only, and no theory has a living chance among us, if results do not follow its application.

It is for this reason that I submit this treatment to the profession. From what I have personally seen in my own practice, and from what has been told or written to me by scientific men for whom I have respect, I confidently believe this method of treatment will afford the best result yet obtained, not only in the cure of phthisis and other forms of tuberculosis, but of other diseases of germ origin. The possible curative range of the fluid is obviously very wide.

It is now in the hands of about fifty physicians, in different parts of the country. I will leave for a subsequent report the descriptive histories of a number of cases included in the following summary.

The total number of cases that have been and are being treated with this fluid which have been reported to me to date, is 216. Of these, improvement is reported in 212 cases, and no improvement in 4 cases. Of the improved cases, 23 have been discharged cured; 66 will, in the opinion of the attending physician, be discharged cured; and in 91 cases, while improvement is noted, no definite prognosis can be made yet. In 32 cases the improvement was only temporary. Of those in which no improvement has been noted, 1 has died.

PUERPERAL ECLAMPSIA.¹

By T. J. BELL, M.D.,

TYLER, TEXAS.

MR. PRESIDENT, AND GENTLEMEN OF THE NORTH TEXAS MEDICAL ASSOCIATION: In response to an invitation extended to me through your worthy chairman of this Section, Dr. J. T. Wilson, to read a paper before your honorable body, I propose to discuss an old and recognized disease of the puerperal state, viz., eclampsia. Not that I expect to convince your minds that what has been held and written upon the etiology, pathology, or treatment of this most formidable malady has been done in ignorance, or has been the result of altogether erroneous investigation. Nevertheless, it is very apparent to any one searching for light upon the subject that there is no disease or condition upon the pathology of which there is greater disagreement or diversity of opinion than puerperal eclampsia.

Until 1843, when Lever discovered albumin in the urine of patients with eclampsia, there was perhaps no well-defined opinion as to the cause of convulsions in puerperal women.

It was then thought that the key to the etiology of the disease had been discovered, but later researches have proved that the relation between albuminuria and eclampsia is not so universal as was once supposed, or at least some other factor was necessary to explain many cases.

Numerous cases were observed in which albumin was detected in large quantities, without any convulsions attending or following, and Braxton Hicks was of opinion that albumin and convulsions appear almost simultaneously, and could only be explained in one of three ways, viz.: 1. That convulsions are the cause of the nephritis. 2. That convulsions and nephritis are produced by the same cause, *e.g.*, some detrimental ingredient circulating in the blood, irritating both cerebro-spinal system and other organs at the same time.

3. That the highly congested state of the venous system, induced by the spasm of the glottis in eclampsia, is able to produce the kidney complication. More recently, Traube and Rosenstein have advanced a theory of eclampsia, purporting to explain these anomalies. They refer the occurrence of eclampsia to acute cerebral anæmia, resulting from changes in the blood incident to pregnancy; the primary factor is the hydraemic condition of the blood, which is an ordinary concomitant of the pregnant state, and, of course, when there is albuminuria the watery condition of the blood is greatly intensified, hence the frequent association of the two states. Accompanying this condition of the blood there is increased tension of the arterial system, which is favored by the hypertrophy of the heart, which is known to be a normal occurrence in pregnancy. The result of these combined states is a temporary hyperæmia of the brain, which is rapidly succeeded by serous effusion into the cellular tissue, resulting in pressure on its minute vessels, and consequent anæmia. There is much in this theory that accords with the most recent views as to the etiology of convulsive disease, as, for example, the researches of Kussmaul and Tenner, who had experimentally proved the dependence of convulsions on cerebral anæmia, and of Brown-Séquard, who showed that an anæmic condition of the nerve centres preceded an epileptic attack.

But, referring to Verrier's fourth edition, as revised by Partridge, of New York, we find that he gives, as predisposing causes: 1. Primiparae, stating that eight out of ten cases are primiparae. 2. Persistent albuminuria, uræmia, and uranæmia, and that many women have considerable albumin in their urine but no uræmia in their blood, and these are not attacked with eclampsia. As exciting causes he places rickets first; then the pressure of the womb upon the viscera and nerve plexuses; and, third, plethora, followed by cerebral congestion, perhaps resulting from either painful distention of the womb during pregnancy, vigorous contractions rendered inefficient by some obstacle, as abnormal rigidity of the cervix, certain obstetrical operations, etc. But, notwithstanding these very sanguine statements by men in the front rank of the profession, we have these words from William L. Richardson, of Boston, in 1889: "The profession is not yet in accord, either as to the etiology or the treatment of puerperal eclampsia." Santos, he says, believes, from a very careful study of fifty-three cases which have occurred in the clinic at Buda-Pesth, that albuminuria occurring in pregnancy is the result of a reflex irritation of the sympathetic and renal nerves; this irritation is due to the irritation of the uterine nerve, incident to its enlargement, and, later, to its contraction and retraction; that eclampsia is, as it were, an acute peripheral epilepsy, having its origin in the uterus.

Albuminuria, according to this idea, is a physiological condition in pregnancy, and, in fact, is of diagnostic value.

Lusk and others believe that it is renal insufficiency and not albuminuria which causes uræmia and subsequently convulsions. Pajot believes the cause is reflex, culminating in a cerebro-spinal centre in close proximity to the disorganized centre, which presides over the existence of albuminuria; in other words, he believes that albuminuria simply predisposes to attacks, but does not act as the exciting cause.

After reviewing the opinions as given by the foregoing authorities, it is evident that the time has not yet come in our profession when any one can say, without doubt, "Eureka," in regard to the etiology of puerperal eclampsia.

Papers have been read and discussed in our State Medical Association—one by Dr. J. D. Bass, at the session of 1886, in which he quotes from Professor

¹ Read in the Section on Obstetrics at the meeting of the North Texas Medical Association in Greenville, Texas, Dec. 10-12, 1895.

Meigs, that it was the result of engorgement, or a hyperæmic condition of the kidneys, and an increased impetus sanguinis of the circulation, and a result, says Dr. Bass, rather of the quantitative than of the qualitative condition of the blood. This I believe to be nearer the truth than anything that has been heretofore written upon the subject. Whether the primary cause is the engorgement of the kidneys in all cases—of this I have some doubt—there is no doubt in my mind as to the increased flow of blood to the brain being the exciting cause in all cases of puerperal eclampsia.

There are few women, perhaps, in the gravid state who do not have œdema gravidarum to a greater or less degree, and yet I cannot think that it necessarily follows that every pregnant woman must have albumin in her urine in order to account for this œdema. Whether there be pressure upon the kidneys or upon the blood-vessels supplying the kidneys or returning the blood from them, there is always more or less pressure by the heavily loaded womb upon the veins passing out of the pelvis and distributed to the lower extremities, thereby obstructing the return of blood from these parts, and that blood stasis maintained for several months will necessarily produce an œdema of the feet and lower legs. Neither do I believe the generally accepted theory that the blood of pregnant women is necessarily hydræmic; this I regard as the opposite extreme of the antiquated theory of plethora in all women in the gravid state. A happy medium between the two theories will perhaps accord more nearly with facts.

There are, I think, unquestionably two classes or conditions in the puerperal state that predispose to eclampsia—one is anæmic, and the other plethoric. Of the plethoric, I believe the larger number are primiparæ; how frequently we have seen young women, who were in vigorous health, blood rich so far as we can discover in all its physiological elements, either with the first pains of labor, or it may be later on, to our utter astonishment and horror, have a convulsion or eclamptic fit. Certainly we could not reasonably conclude that such a robust and healthy-looking woman had been suffering with kidney trouble, or albuminuria, or hydræmia. No, indeed; her kidneys are all right and her blood is all right, but at the inception of labor, when the nervous system has been taxed to its utmost for eight or nine months, the reflex irritation brought about by the irritation of the uterine nerves is conveyed to the brain, producing cerebral excitement, the heart receives the impression, and with increased energy it propels the rich blood to that great nerve-centre, until we have an active congestion or hyperæmia; and the woman, as a result, has convulsions. In the other class, generally, I believe, multiparæ, we find an anæmic or bloodless condition; really whether there is an abnormal diminution of the quantity of the blood in the body or not, there is certainly hydræmia, or a condition of the blood in which the watery constituents predominate.

This hydræmia, whether brought about by renal insufficiency, nephritis resulting in non-elimination of urea by the kidneys, or the depletion of the blood of its most important element, albumin, I am not prepared to discuss; however this may be, we always, I believe, find in these cases more or less albumin in the urine, and I think we may reasonably conclude that in this class of cases there is always more or less kidney complication. This deteriorated blood being deficient in its nutritive elements, an increase in the quantity is demanded to compensate for the lack in quality; and, at the same time, urea perhaps being in excess in the blood, irritating the already over-sensitive brain, the demand is made upon the heart, and we have a greater quantity of the poor watery fluid propelled by the heart through the arterial system than

the over-filled and weakened veins are able to return; and the consequence is blood stasis or passive congestion, and the poor bloodless creature has convulsions in consequence of the pressure upon the brain.

As to the symptomatology and treatment of these two types of eclampsia, I am of opinion that as we will almost invariably find a different train of symptoms in these two types, so should our treatment be almost entirely different; for instance, in the plethoric type we have a full-blooded, robust, healthy woman, with a heart equal in force almost to a small engine propelling the rich red blood throughout the system, and up to the very moment almost that her whole frame is thrown into a convulsive state, she is perfectly well, no symptom of disease; then her face and eyes become a diffused red, almost purple, hue; her heart beats violently, with a full, bounding pulse at the wrist; while in the anæmic type we find our patient has been feeble for some time previous, with a very poor appetite, headache a great deal of the time, face pale and swollen—in fact, has a dropsical appearance generally. The heart-beat is too fast, but not full and strong, and frequently complaint is made of dizziness or spots before the eyes for several days before the convulsions come on; then when the convulsions do appear, the face, instead of being of that diffused redness described in the plethoric type, is pale and looks almost like chalk or marble, while the heart is beating still more rapidly, and the pulse at the wrist is small and frequently so rapid that we can hardly count it. We find also in this class of cases a scanty flow of urine which is always, I believe, loaded with albumin to a greater or less degree.

In the management of these cases of eclampsia there is, as above stated, great diversity of opinion. Some men very prominent in the profession will bleed indiscriminately, while others equally prominent do not bleed at all.

At the meeting of the Texas State Medical Association, at San Antonio, in 1889, a paper on eclampsia was discussed, and these two extremes were very apparent. In plethoric, full-blooded, healthy women attacked with convulsions, when there are no symptoms of labor present, the most speedy relief perhaps would be to draw blood from the general circulation until the arterial tension has been reduced. After this has been done, I would give chloral hydrate and potassium bromide in large doses to quiet the nervous system, tincture of veratrum viride in large doses—say eight to twelve drops repeated at intervals of six to twelve hours, as is necessary to control the heart's action and keep the pulse from 60 to 80 beats in the minute. I also give a full mercurial course to unload the bowels and at the same time relieve any congestion that may exist in the renal circulation.

Generally it is not the safest to induce labor in these cases; however, if labor has set in and the convulsions continue, the womb should be emptied of its contents as speedily as is consistent with the welfare of the mother and child. There should be no iron rule governing us in the obstetric management of these cases; each individual case should be managed consistent with indications.

In a paper published in one of our Texas medical journals recently, an eminent professor in a St. Louis medical college asserts that "puerperal eclampsia can be cured, if taken in time, by the following methods:" and then goes on to say that chloroform should be given and the uterus emptied at once, even if it requires Cæsarean section to accomplish this end.

He makes no compromise and allows no latitude, whether the woman is at full term or only a few months pregnant; whether she is in labor or whether there is no symptom of labor, his rule, like the law of the Medes and Persians, cannot be changed.

I do not believe we are warranted in resorting to such radical measures in every case of puerperal eclampsia, and I do not believe there is a member of this Association who has seen many cases of puerperal eclampsia who would be guilty of such practice. In the first place, it is not sure that emptying the uterus will stop the convulsions; and in the second place, we know that speedy delivery of an immature fœtus means taking the life of a human being, whereas we may save the life of both mother and child by more conservative procedure.

In the anæmic type, as described in the foregoing page, general blood-letting should never be practised, for the reason that depletion of the vascular system would tend to increase the hydræmia, and could only be a temporary relief, if any at all, and more than likely would lessen chances of recovery.

Instead of bleeding a woman in this condition, give hypodermically from ten to fifteen drops of tincture of veratrum viride, to reduce the frequency of the heart-beat to 60 or 80, and repeat in quantity sufficient and at such intervals as will be necessary to maintain this impression, until other remedies can have time to act. Instead of large doses of calomel, as is necessary in the plethoric type, smaller doses repeated at intervals sufficient to act gently upon the bowels, and more particularly to act as a diuretic; moderate doses of potassium bromide and chloral hydrate to quiet the nervous system; digitalis, potassium bitartrate, or other diuretics and laxatives, tincture of chloride of iron, and other tonics, and the indications will have been met.

I have used hypodermics of morphine sulphate to control nervous symptoms with good effect.

As this class of cases is generally, or frequently at least, seen in multiparæ who have not advanced to the full term of gestation, the question will naturally arise as to their obstetric management. More often than otherwise, perhaps, there are no symptoms of labor when the convulsions make their appearance. On examination, we may find our patient at the fifth or sixth month of pregnancy, with a soft, dilatable, but undilated os, and no uterine contractions whatever. In such cases it is wise to let the fœtus alone, unless, in spite of all efforts to relieve the woman with other remedies, the convulsions continue to recur, and the mother's life is in great peril; then, and only then, are we justified in producing abortion, for it is only a question of a few days, perhaps, when labor will come on, and the fœtus will be expelled naturally. On the other hand, if the convulsions are controlled and labor does not succeed the eclamptic attack for several months, we may save two lives instead of one, as we surely would have destroyed the child if we had delivered at the fifth or sixth month of gestation, and would have stood a good chance of losing the mother also. After labor has been completed in this class of cases, there is usually not much danger from convulsions, but sometimes we shall find it necessary to watch our patient for weeks and perhaps months, occasionally finding it necessary to reduce the frequency of the heart-beat, and always to use means to correct the kidney trouble and tone up the general system.

Since this paper was written I have seen a paper, as read before the Alumni Society of Bellevue Hospital, by Dr. C. C. Barrows, in which he relates two cases—one in which he incised the cervix laterally and antero-posteriorly, while in the other case the canal was dilated manually. In either case, however, the delivery of the child failed to stop the spasms, and it was only when he resorted to large doses of tincture of veratrum viride that he was able to control or put a stop to the convulsions. In discussing this paper, Dr. J. Clifton Edgar stated that only about two years after Dührssen had published his article advocating the use of deep incisions into the cervix, his further experience

had had the effect of dampening his enthusiasm, and after that time he had advocated their use only in extreme cases. Dr. Edgar believes it is only in very exceptional cases that the obstetrician is justifiable in dividing the lower uterine segment from the external os to the utero-vaginal junction. The operation, he believes, is extremely limited in its usefulness, as it is applicable only to cases in which the internal os has already been dilated. There must be this preliminary dilatation. He does not believe that any drug, except possibly chloroform, is of as much value as veratrum viride in eclampsia.

It would seem from the discussion of this paper that the value of veratrum in puerperal eclampsia had not been generally known; doubtless the usefulness of the drug had been overlooked merely in the North and East, notwithstanding many Southern physicians had been using it for years.

REPORT OF CASE OF SUPPOSED ABSCESS OF LIVER, LAPAROTOMY, EXCISION OF PIECE OF LIVER, WITH RELIEF OF SYMPTOMS AND COMPLETE RECOVERY.

By GEORGE L. PEABODY, M.D.,

NEW YORK.

THE patient who forms the subject of these remarks is a policeman in the service of the park department, a native of Ireland, unmarried, who was twenty-nine years of age when he came under observation in the New York Hospital, in October, 1892.

Prior to the illness that I shall briefly describe to you, his general health had been excellent; he had had occasional attacks of diarrhœa, but otherwise had been always well.

The illness for which he sought relief in the hospital had commenced without known cause on August 6, 1892, about two and a half months before he was observed by me. At that time he began to suffer from abdominal cramps. These were followed in twenty-four hours by a severe chill, fever, and sweat. In a few days there developed a very marked tenderness to pressure in the right hypochondrium, which continued to grow steadily worse during the weeks of illness that preceded his admission to the hospital. During the first five or six weeks of his illness he had frequent sharp chills, which were always followed by fever and sweating. These paroxysms were of irregular occurrence, sometimes coming twice in twenty-four hours and sometimes allowing a day or more to intervene between them. They were thought by his physician to be malarial, and on that supposition he received full doses of quinine, *z. e.*, thirty-six grains a day for three weeks. The frequency and severity of the paroxysms were not modified by this treatment.

In addition to the tenderness in the right hypochondrium to which I have alluded, he complained of having suffered for two months from a steady, continuous pain just below the ensiform cartilage, which seemed to associate itself with the tender area to the right of this spot. For two weeks prior to admission he had complained of pain in the right shoulder.

During his entire illness he had suffered from complete anorexia and had lost sixty-five pounds in weight.

On admission to the hospital on October 21, 1892, his whole liver region was painful and very tender to pressure. Liver dulness began at the fifth intercostal space in the mammillary line and extended one and one-half inches below the free border of the ribs. The spleen was not palpable. The patient was greatly emaciated. No other abdominal and no thoracic lesion could be made out.

¹ Read at a meeting of the Practitioners' Society, Friday, January 3, 1896.

His bowels were regular; his appetite poor; his temperature was 99.2° F., and his pulse 96 and compressible.

His urine was normal. He had no chills after he came under observation, but his temperature frequently rose several degrees above the normal and his pain and tenderness in the hepatic region did not vary; the pain in the right shoulder continued.

He was observed for ten days, during which time there was no material change in his condition. At the end of this time, with the concurrence of Dr. Bull, he was transferred to one of his wards for operation. It seemed to us that the character and duration of his symptoms pointed strongly in the direction of hepatic abscess; and with that diagnosis Dr. Bull performed laparotomy on October 31st, eleven days after he came under observation.

The liver was exposed and found to occupy the space indicated by the physical examination.

The surface of the left lobe was studded with minute white dots, not elevated above the surface and suggesting the appearance of miliary abscesses or very young tubercles. The surface of the liver was smooth and presented no point of bulging. A medium-sized aspirator needle was thrust deeply into the left lobe and subsequently into the right. The aspirator withdrew a small amount of blood in each case, and nothing else.

A small elliptical piece of liver tissue was removed containing several of the minute white spots and was sent to the pathologist of the hospital, Dr. Ferguson, for examination. He hardened it and examined sections, and reported that it contained many microscopic aggregations of small round cells which looked like minute abscesses.

The wound healed slowly, the fever and pain and all of the other symptoms disappeared, and the patient was discharged from the hospital on November 23d, apparently well. He had had no recurrence of any of his symptoms while he remained in the hospital after the operation.

He re-entered the hospital on the medical division on December 2d. After leaving the hospital he continued to feel well for four days, when pains, more or less colicky in character, developed in the abdomen, chiefly on the left side and in the back. His appetite was good and his bowels constipated.

His liver appeared to be normal in size. There was tenderness in the left iliac fossa.

He was purged and treated subsequently only with placeboes, and a carefully restricted diet. During the next three weeks he had much fever of an irregular type, his temperature often rising above 104° F., and there being no fever often for days together. Toward the end of December all symptoms again disappeared, and he again left the hospital.

During the last three years I have seen him frequently; the last time only two days ago. He has been in perfect health all of the time, and is now absolutely strong and well and has regained his normal weight. He tells me that he has not lost a single day during these three years, and that he never felt better in his life. I did not ask him to come here this evening because several other patients were expected, and, moreover, a careful examination of him conducted within ten days revealed no abnormality, except the scar of the abdominal incision.

It seems to me that most of his prominent symptoms suggested naturally the diagnosis of hepatic abscess or pyelophlebitis, especially the pain and tenderness and swelling of the liver, the septic fever, the pain in the right shoulder, and the emaciation. The nature of his malady is still a mystery, and also the relation, if there be any, between the treatment to which he was subjected and his recovery.

ANTIPHTHISIN IN TUBERCULOSIS.

By C. P. AMBLER, M.D.,

CANTON, OHIO.

For some six months past I have made use of antiphthisin in the treatment of several cases of pulmonary and local tuberculosis, with results so gratifying that I believe it my duty to call the attention of the profession to this remedy, by the following report of cases treated, which includes all as they came under my notice. It is not my intention to enter into theoretical considerations as to the action of the remedy, and refer the reader to several publications by Dr. Karl von Ruck,¹ of Asheville, N. C., and also by Professor Klebs,² for such additional details.

In my clinical use of antiphthisin, I have noticed no unfavorable influences whatever.

CASE I.—Male, aged twenty-three: gave the following history: Family history fairly good; patient had enjoyed good health until March, 1894, when he had typhoid fever, from which he dates the beginning of the present affection. A year ago he sought a change of climate, going to Asheville, N. C., but he gradually became worse, when, after two months, he had become confined to bed, and at that time entered the Winyah Sanitarium, under the charge of Dr. Karl von Ruck. He remained there two months, during which time he was treated with antiphthisin, and his improvement there was rapid and satisfactory. Returning to Canton, Ohio, his home, he was referred to me for further treatment with antiphthisin. I examined this patient in June last, for the first time, and found a good-sized cavity in the left upper lobe, with dulness on percussion, both anterior and posterior; there was dulness also in the lower portion of the left lower lobe. Throughout this lung I found bronchial and broncho-vesicular respiration, with râles and crepitations. The right lung, too, showed unmistakably infiltration of the upper lobe; the middle and lower lobes were comparatively free. Temperature ranged from 97° to 101° F. Pulse, 106 to 120. Weight, 114 pounds (former weight in health, 148 pounds). Cough frequent and expectoration profuse, showing tubercle bacilli in considerable numbers. Digestion fair. Expansion of chest, one inch.

From the statement of the patient that he was much improved over his condition when he was first treated with antiphthisin, it may be inferred that the case was a very unfavorable one, and I so considered it at this time. No other medication was employed.

Antiphthisin in doses from 0.5 c.c. to 2 c.c. daily per rectum was administered, with few short intermissions to the present time.

A gradual improvement of all symptoms was observed, and has been uninterrupted to the present time.

Examination now shows entire absence of all râles and crepitations, the evidence of infiltration on the right side has entirely disappeared, percussion and auscultation giving normal conditions. The lower lobe of the left lung has also gradually been clearing up, so that at this time there is a fair respiratory murmur throughout. The cavity in the left upper lobe, of course, remains, but there has been no further breaking down of tissue, and the greatly diminished secretion justifies the belief that cicatrization is taking place. The surrounding area has become clearer from month to month. The temperature now does not exceed 99° F.; pulse, 80 to 96. Cough is confined to early morning and expectoration is so little that it is difficult to obtain a specimen for examination. Chest

¹ Therapeutic Gazette, March 15, 1885; Cincinnati Lancet and Clinic, June 15, 1895.

² Journal of the American Medical Association, October 12, 1895.

expansion has increased to two and one-fourth inches, and weight from 114 to 124 pounds.

The case to me appeared to be a hopeless one, in the beginning of my connection with it, but there is now every prospect of continuous improvement.

CASE II.—Female, aged twenty-seven. Examined first, July 14, 1895. States that she has had enlarged glands in supra- and infra-clavicular spaces and axilla on both sides, for about six years, the condition gradually growing worse. Father died of tuberculosis. At the first examination I counted thirty-seven enlarged glands, the largest of the size of a walnut, and a number of them quite tender and painful. One in the left axilla was so large and tender that the patient had to hold her arm out and away from her body.

In addition, there was evidence of pulmonary tuberculosis; a short percussion note and harsh respiration were observed in both apices. Temperature ranged from 97.8° to 99.5° F. Pulse, 92 to 108. Respiration, 18. General nutrition fair, but patient complained of being weak.

Dr. von Ruck, of Asheville, who happened to visit me at that time, saw the patient with me, and gave it as his opinion that the case was one of glandular tuberculosis, with beginning involvement of both lungs, and advised the administration of antiphthisin, which was done, to the exclusion of all other medication, beginning with 0.5 c.c. hypodermically and increasing to 1 c.c. Twelve of the glands also were injected directly with doses varying from 0.2 to 0.8 c.c.; one gland softened and broke down, and contained cheesy debris, which was evacuated by curettage. Tubercle bacilli in large numbers were found in the liquid discharge. The cavity was repeatedly curetted and packed with cotton soaked with antiphthisin, and it soon healed.

At the end of the first month of treatment, the circumference of the neck had diminished from fifteen and one-half to fourteen inches; many of the glands had entirely disappeared. The patient was now given an intermission of three weeks in the treatment, when, upon resuming the treatment, several of the glands again became enlarged during the first week of the injections, but disappeared thereafter. The treatment after the intermission continued three weeks; her pulse and temperature were then normal, the neck measured only twelve and three-fourths inches, and a gain in weight of twenty-three pounds had been made. Patient feels strong and well. There are still three quite prominent glands on the right side of the neck, two behind the left ear, two each in the right and left axilla. These glands have not changed at all from the first, and I hesitated to inject them directly, fearing they breaking down, as did the one previously mentioned. A letter from her husband, dated November 28th, states that she still continues to improve.

CASE III.—Male, aged forty. Patient presented himself August 3, 1895, with an ulceration extending over about half of the conjunctival surface of the lower lid of the left eye, involving the cartilage and also the integument to the extent of half a finger breadth; the ulcerations had existed for more than a year, and treatment at the hands of several physicians had proved without avail. The ulcer appeared scooped out, presenting but little inflammatory action, was bathed in pus and was not particularly painful. Ordinary dressings and remedies were applied, including curettage and cautery, without improvement. At the end of a month, on September 3, 1895, no improvement having taken place and tuberculosis being suspected, the pus was examined and quite a number of tubercle bacilli were found. Under local application of antiphthisin daily, the ulcer rapidly improved and was completely cicatrized on September 25th, when the patient was discharged. No relapse has occurred to the present time.

CASE IV.—Lady, aged twenty-six, presenting chronic ulcer upon the chin. In perfect health otherwise. Consulted me, September 9, 1895. The ulcer, which had existed since December, 1893, was said to have started from a pimple. At times almost healing over, it always opened again; it had previously been cauterized with caustics and galvano-cautery, powdered, washed and dressed, and anointed, but all without benefit. I made several microscopical examinations of the discharge, but could not find any tubercle bacilli. Nevertheless, the patient having a tubercular family history, and in view of my experience in Case III., I determined upon local treatment with antiphthisin. At the end of a week there was already unmistakable evidence of improvement, and on October 20th the ulcer had entirely healed, leaving only a slight depression as the evidence of the former obstinate trouble. At this time, December 3d, there is no evidence of relapse.

CASE V.—Male, aged forty-two, a gentleman of high intelligence, consulted me, November 8, 1894, for a discharge from the middle ear. Had been in poor health for about five years, having to spend part of his time in travel in order to recuperate. Weight, 110 pounds.

Had been treated for his ear affection by several prominent aurists, both at home and abroad, with only slight and temporary relief. I found perforation involving about one-fourth of the tympanum; the incus and stapes were both destroyed. The discharge was not profuse, but sufficient to be a constant annoyance. I treated him irregularly until September 1, 1895, with only temporary relief. At this time I examined the discharge for tubercle bacilli, but found none, and resolved to try antiphthisin. Local applications were made upon a pledget of cotton, the same being left in position. At the end of three weeks, all discharge had ceased, but the applications were continued until October 16th, and since that time to the present there has been neither discharge nor pain.

CASE VI.—Female, aged fifty-four, consulted me last July for troublesome cough and labored breathing. She had been treated for the year past for asthma and bronchitis, and during this time had lost twenty pounds in weight. Temperature at time of examination, 100.5° F.; pulse, 124; respiration, 32. She was unable to sleep except by short naps, on account of constant cough. Expectoration was variable in amount, at times but little, and at other times very profuse. Both upper lobes presented evidence of consolidation, the left side being apparently solid. No cavity could be demonstrated; the microscope showed large numbers of tubercle bacilli in the sputum.

Antiphthisin was given hypodermically in doses beginning with from 0.2 to 1 c.c. In the course of the treatment the temperature varied greatly between 100° and 104° F. as maxima, both with and without the injections. The treatment was continued until November 1st last, when she joined her husband in Washington, D. C., where she is to spend the winter. During the last month the temperature became better, and whereas in the beginning she found it difficult and fatiguing to come to my office in a carriage, she now walked the distance of a mile from her residence to my office without discomfort. The character of breathing had greatly improved, the frequency of the respirations having been reduced to 22 per minute; her expansion had increased from practically nothing to one and one-half inches.

The local area of involvement in the right upper lobe has entirely cleared, the respiratory murmur being normal. The left side shows slight improvement, the respiratory murmur being distinguishable in the lower lobe. The secretion from the upper left lobe is profuse, but no cavity has been demonstrable.

This patient was additionally treated with the pneumatic cabinet, which quite likely had a contributory influence in her improvement, especially of chest expansion.

CASE VII.—Female, in apparently good health, presented herself August 24, 1895, with a large ulceration on the right side of the nasal septum, involving part of the bony and part of the cartilaginous portions. The ulcer was about three-fourths inch long and one-half inch wide, with scooped-out appearance. A year ago she had some catarrhal trouble following an attack of influenza, and had picked her nose frequently at this spot, which was often followed by bleeding, and it had remained sore ever since. Washes, douches, and sprays had been used without benefit. She has a brother suffering from phthisis. Microscopical examination of the dirty gray mass which covered the ulcer revealed a few tubercle bacilli. After thorough cleansing antiphthisin was applied locally every day for three weeks, under which the ulceration healed from the edges, so that it was greatly reduced in size and of a healthy appearance. At this time she left the city, and I saw her last on November 16th. The ulceration had now entirely healed, and but for a slight depression I could not have told where it had been situated.

In addition to these finished cases, I have others under treatment, with corresponding prospects of success, which I propose to report in the future in their order of discharge, and, while the number of reported cases is small, they nevertheless appear to me of interest, especially those of local tuberculosis, in several of which a microscopical diagnosis was possible. Such cases heretofore, as a rule, have not been suspected as of a tubercular character, and I trust that others may be induced to apply this remedy in such obscure cases, thereby, perhaps, aiding in the directions of both diagnosis and of treatment, the latter being in my hands exceedingly simple and rapidly satisfactory.

Progress of Medical Science.

Cœliotomy with and without Drainage.—Dr. Czempin refers to the great fluctuations of opinion of authoritative operators, and notes that drainage is being less and less employed each year. He refers to the method advised by Säger (the glass drain) and Mikulicz (the iodoform-gauze drain), and also to the indications for drainage as pointed out by Veit, Olshausen, and Martin. He notes that Säger employs this form of drainage no more; that he has practically discarded drainage; that Veit believes the indications are very few; and that opinions are so varied that there are no fast rules to follow in any particular case. Czempin, through a period of nine years of operative work, has at times followed the advice of each of the above investigators, and has carefully studied the subject. He has found that each year fewer cases require the drainage-tube. From his observations the cases in which drainage may be indicated are divided into two great groups. First, operations upon non-infectious tumors, with unfavorable complications caused by the condition of the relations of the operation wound. Second, operations upon infectious tumors or those thought to be infectious, and operations complicated through injury to the intestine, the escape of pus or decomposed fluid. First, complicated non-infections operations. To this group belong (a) intra-ligamentary-developed new growths resulting in the necessary extensive separation of the pelvic connective tissue; (b) where the new growth has extensive adhesions with neighboring organs and the parietal peritoneum, therefore necessitating extensive injury to the peritoneum. Under these headings the

writer reports a series of cases with results which vary too much to be of practical use. In the first group, the separation of the pelvic connective tissue and the extensive wound results in the formation of the best culture medium for infectious organisms, and that infection takes place either through faulty technique, infection from without, or through intestinal bacteria, the result of injury to the intestine. He says that it is doubtful whether drainage does good in these cases; that the resulting exudate is quite as readily absorbed and eliminated by nature. As regards the second group of cases, he refers to the statistics of Zweifel of one hundred and three adnexa operations, with one death, where the rubber drainage-tube was employed, but says it proves nothing. The method of Schauta, Wertheim, and Fritsch (the microscopical examination of pus during operation) he believes has the correct object, but is not positive; that the organisms may not be virulent, they may be few in number and not found, and a certain number of cases are thus unnecessarily drained. The use of drainage complicates the operation, often causing suppuration in the abdominal wound, fistula, and hernia. Finally, he concludes that the result in complicated cœliotomy is only rarely improved by the use of drainage, and that in the greater number of cases where it is used it is not essential. If virulent organisms are present, it can scarcely save life; if the virulence is extinct, it is not necessary. Where in the removal of a non-infectious new growth the pelvic connective tissue is separated, drainage is not only unnecessary, but often does harm. Where there is a closed-off acute inflammatory process in a tumor in the peritoneal cavity and in its removal pus escapes into the peritoneal cavity, infection is to be feared. Particular caution should be taken that the least amount of the peritoneum is infected, and the material should be carefully removed with the sponge. The use of the iodoform-gauze tampon does not physically or chemically influence the result. The opening of acute inflammatory connective tissue in adnexa operations is very dangerous. Whether drainage can save the patient's life is questionable. In such cases he believes complete hysterectomy gives the best results. In adnexa operations he advises that the operation be performed six months after the last exacerbation. In cases in which the pelvic connective tissue is widely separated in the removal of a tumor (hematoma of the broad ligament) drainage is not necessary. In very difficult operations, where the pelvic connective tissue is widely separated and the case is septic, the best results are gained by complete hysterectomy and drainage with iodoform gauze through the vagina.—*University Medical Magazine*.

Asbestos as a Surgical Dressing.—Dr. E. O'N. Kane, of Kane, Pa., recommends asbestos as a practical and useful substance for surgical dressings. These dressings, he says, may be carried in any parcel, paper bag, or hand-satchel, may be handled by dirty hands, spattered by blood or any sort of filth, and yet can be rendered absolutely aseptic in less than two minutes by tossing them upon the coals or into the blaze of an ordinary kitchen stove. After having completed an operation, and just before he is ready to apply the dressings, they are thrust into the coals or flame of the nearest stove. The same dressings can be used, if necessary, though here it is advisable to wash off some of the discharges before the dressings are burned. Repeated burnings seem to injure the quality of the material somewhat. The form of asbestos most used is the asbestos fibre, which is as soft as silk floss, and its absorbent qualities are greater than those of absorbent cotton. Asbestos wicking, packing, and cording are adapted for drainage tubes.

EXPIRED AIR AND ITS EFFECT UPON ANIMAL LIFE.¹

It was a wise grant from the Hodgkins Fund to provide means for "an investigation into the nature of the peculiar substances of organic origin in the air expired by human beings, with special reference to the practical application of the results obtained to problems of ventilation for inhabited rooms." The results in the paper before us prove that this important investigation was entrusted to the proper persons. We need not emphasize the evil effect of what is usually called bad ventilation; it is, perhaps, true that acute diseases are not to be traced to the same, but it may be safely stated that there is a distinct deterioration of vital forces in those who are constantly subjected to the impure atmosphere of badly ventilated rooms. The cause of the sickening sensation which comes over us upon entering an atmosphere contaminated with many breaths, or of the gradual deterioration of the vital forces which follows confinement in such an atmosphere, is not known. For a number of years prior to 1888, the view prevailed that the discomfort and danger to health and life in badly ventilated rooms were largely due to organic matters contained in the air expired, and that the increase in carbonic acid due to respiration has but little effect in producing the bad results. Recently, however, several experimenters have concluded that the organic matters in the exhaled breath are not harmful, at least to animals. According to the authors of this paper, the effects produced on animals and men by an atmosphere contaminated with their exhalations, and with particulate matters derived from their bodies or their immediate surroundings, may be divided into acute and chronic. The acute effect may be death in a few minutes or hours, as in the Black Hole of Calcutta, in the steamer Londonderry, and as in many of the experiments referred to in this report; or it may be simply great discomfort, especially in those unaccustomed to such conditions. In this connection the authors show the curiously interesting fact that in mice which had been subjected to a foul atmosphere a certain degree of immunity is obtained, a fact which clinical experience would seem to confirm. The workers in sweatshops, for instance, tolerate month after month a vitiated atmosphere which makes any person en-

tering the room for the first time extremely ill. As for the chronic effects of inhaling a contaminated atmosphere, the authors say that they include the favoring of the action of certain specific causes of disease known as contagious, if these are present, and, perhaps, also, a general lowering of vitality. The general results of this particular series of experiments indicate that in air expired by healthy mice, sparrows, rabbits, guinea-pigs, or men, there is no peculiar organic matter which is poisonous to the animals mentioned, excluding man, or which tends to produce in these animals any special form of disease. This contradicts the historical experiments of Brown-Séquard and d'Arsonval, who believed that their work proved the source of poison in the exhaled breath to be a volatile organic poison, of the nature of an organic alkaloid or a ptomaine. On the other hand, in these experiments, the injurious effects appear to be due entirely to the diminution of oxygen or the increase of carbonic acid, or to a combination of these two factors. It would also seem improbable that the small quantity of organic matter in the air expired from human lungs has any deleterious influence upon men who inhale it in ordinary rooms. And hence it is not necessary to take this into account in providing improved ventilation for such rooms. It seems that the air in an inhabited room, such as a hospital ward, receives its chief source of contamination from the particles of dust which naturally include some of the bacteria which produce inflammation and suppuration, and the authors think that these are the only really dangerous elements in this air. The experiments in which animals were compelled to breathe air vitiated by the products of their own respiration or by those of other animals again go to prove that there is no peculiar volatile poisonous matter in the air expired by healthy men and animals, other than carbonic acid. And the authors conclude that the evidence which has heretofore been supposed to demonstrate the evil effects of bad ventilation upon health should be carefully scrutinized. The bad effects of increase of carbonic acid and reduction of oxygen are greatly increased by excessively high or low temperature, and the relation between the carbonic acid increase and the diminution of oxygen which has been found to exist in badly ventilated churches, schools, or barracks, does not satisfactorily account for the great discomfort which such conditions produce in many persons. Nor has the amount of change in the normal proportion of these gases any influence upon the increase of disease and death rate which is known to exist among persons living in crowded rooms. It would seem, indeed, that the diseases of the lungs which are so prevalent among such people is due to the special liability of such rooms to become infected with the germs of these diseases, *i.e.*, of consumption and pneumonia, which are caused by specific bacteria. It is interesting to note in this connection that tuberculous disease of the lungs and pneumonia attack those living and working in unventilated rooms, provided they are not members of the Jewish race.

The results in the paper before us seem to justify the conclusion that the discomfort felt in crowded, ill-

¹ "Smithsonian Contributions to Knowledge, 989," by J. S. Billings, M.D.; S. Weir Mitchell, M.D., and D. H. Bergey, M.D.

ventilated rooms is not due to excessive carbonic acid, nor to bacteria, nor, in most cases, to dusts of any kind, but is, in reality, due to excessive temperature and unpleasant odors. Nothing in these experiments shows the cause of the unpleasant, musty odor of an unventilated room, and attention is called to the curious fact that cases of fainting in crowded rooms usually occur in women, and are connected, the authors think, with defective respiratory action, due to tight lacing.

Finally, these investigations, the authors declare, go to prove that some of the theories upon which modern systems of ventilation are based are either without foundation or doubtful, and that the problem of securing comfort and health in inhabited rooms requires the consideration of the best methods of preventing or disposing of dust of various kinds, of regulating temperature and moisture, and of carrying off poisonous gases derived from heating and lighting apparatus, rather than of simply diluting the air to a certain standard of proportion of carbonic acid present.

We trust that these experiments will receive the consideration they so richly deserve from sanitarians and those who are connected with philanthropic and other institutions in which there are large assemblies of people.

A PHYSICIAN AND BUCCANEER.

In an address delivered before the Historical Club of Johns Hopkins University Dr. William Osler gives an account of Dr. Thomas Dover, whose name has passed down to posterity in connection with *pulvis ipecacuanhe compositus*. There are few physicians who have not prescribed Dover's powders, but there are, we think, still fewer who know much about Dr. Dover, and, especially, who know that he was at one time a successful buccaneer and discovered Alexander Selkirk, of "Robinson Crusoe" fame. Dr. Dover was born in Warwickshire, about 1660, and was probably a student of Sydenham's. After taking his degree, he settled in Bristol and, having made some money, joined with some other merchants in a privateering expedition. Two ships were fitted out, and Dover went as third in command, being styled "Captain Dover." He sailed to the Spanish Main, and in 1709 arrived at the Island of Juan Fernandez. There Captain Dover went ashore, and discovered the sole occupant of the island to be a Scottish sailor named Alexander Selkirk, who had been left there alone four years and four months before. Selkirk was taken off and made an officer on one of the ships. The expedition afterward sacked the two cities of Guayaquil, Dover leading in the assault. They took a number of prizes, and cruised about the coast from Peru to California. They then sailed across the Pacific and reached England in 1711. The expedition was very successful, realizing the enormous sum of \$850,000, of which Dr. Dover received a considerable part. After his return home Dover travelled again somewhat, but finally went to London. His most famous book is one known as "The Ancient Physician's Legacy," published in 1733. This was a popular treatise on medicine, and was intended, appar-

ently, to get practice for the author. The full title of the book is "The Ancient Physician's Legacy to his Country, being what he has Collected himself in Forty-nine Years of Practice." The author says: "The diseases incident to mankind are described in so plain a manner that any person may know the nature of his own disease, together with the several remedies for each distemper, faithfully set down." It is expressly designed for the use of all private families. The "Legacy" is said to have made a great noise in London, and to have been the subject of debate in every coffee house. It contained a description of about forty-two diseases, illustrated with cases which attested the author's skill. The later editions abound with letters from grateful patients, extolling Dr. Dover's virtues. On page 18, in the section on "Gout," is given the formula of his famous powder:

"Take Opium one ounce, Salt-Petre and tartar vitriolated each four ounces, Ipecacuana one ounce. Put the Salt-Petre and Tartar into a red-hot mortar, stirring them with a spoon until they have done flaming. Then powder them very fine; after that slice in your opium, grind them to a powder, and then mix the other powders with these. Dose, from forty to sixty or seventy grains in a glass of white-wine Posset going to bed, covering up warm and drinking a quart or three pints of the Posset—Drink while sweating." The same formula is repeated in the subsequent editions. He says that some apothecaries have desired their patients to make their wills and settle their affairs before they venture upon so large a dose as from forty to seventy grains. "As monstrous as they may represent this, I can produce undeniable proofs where a patient of mine has taken no less a quantity than a hundred grains, and yet has appeared abroad the next day."

Besides the above powder, Dr. Dover's chief legacy to his country was quicksilver, which, in his opinion, was specific in almost every disease. He was accustomed to order an ounce or an ounce and a quarter of crude mercury daily. A case is reported of a man who took for his cough and shortness of breath, altogether, one hundred and twenty pounds weight. Dover was very naturally called the "quicksilver doctor," and received a great deal of, no doubt, well-deserved criticism. Dr. Dover, in his later days, appears to have carried the fighting, if not the buccaneering, spirit into his professional life, and, judged by modern standards, he would be considered very much of a quack. In estimating his moral and professional character, however, we must make due allowances for the times in which he lived.

Encouraging Words.—The MEDICAL RECORD comes to us in its new garb. From cover to cover it shows the touch of a master hand. The type is neat, distinct, and inviting. It is a model of typographic beauty. As to the literary merits of the RECORD, we need say naught. Its past and its present speak for themselves. Time, which is the only true critic, has rendered a verdict for the RECORD of which all concerned with it may feel a just pride, the editor in particular.—N. Y. State Medical Reporter.

DOCTOR, CAN I SMOKE?

UNDER the title of "The Indications and Contraindications for the Use of Tobacco by the Sick and Convalescent," Dr. L. Jankau has published an article in which he tries to answer the question so often asked by patients and convalescents—"Doctor, can I smoke?" Dr. Jankau does not attempt to discuss the problem whether healthy people can smoke, but confines himself to the relations of tobacco to the invalid.

The employment of tobacco, he says, is to be forbidden in all surgical operations and long convalescence after operations, except those practised upon the eyes, the abdomen, and the bladder. He would prescribe tobacco also in affections of the throat and pharynx, and, with certain restrictions, in nasopharyngeal catarrh. As regards internal maladies, he says one should never forget the toxic action of tobacco, so that in acute and serious diseases it should never be allowed—a precaution which is hardly needed, since in most cases where patients are very ill, they quickly lose their taste for tobacco. To particularize the indications and contraindications, Dr. Jankau says, first, that tobacco should be absolutely forbidden in peritonitis, typhlitis, and perityphlitis. Affections of the stomach do not form an absolute contraindication. This opinion, as a critic in the *Bulletin Générale de Thérapeutique* truly says, is quite open to dispute. It is certain that tobacco smoking in excess will produce "heartburn" and various forms of dyspepsia; indeed, Dr. Jankau himself later states that he does not believe in the beneficent action of cigars after a meal. Subjects affected with organic disease of the heart do not ordinarily support tobacco well; at the same time, habitual smokers can use two or three light cigars a day. As to pulmonary affections, the author allows his antiseptic views to have a good deal of weight in guiding his judgment. On the score of the proven fact that tobacco smoke has an undoubted influence in suppressing the development of bacilli, he rather advises smoking for those persons who are in the initial stage of tuberculosis. His reasons are: the disinfecting action of tobacco upon the mouth, the depression exerted by tobacco upon the genital functions; furthermore, the favorable sedative influence of this drug upon the central nervous system. Besides that, he thinks that it tends to take away the attention of patients from themselves and make life seem more agreeable to them. Even slight hæmoptyses are not absolute contraindications for the use of tobacco. While on this subject, the author fails to note the pretty well-tested fact, that smoking sometimes keeps down the seizures of nervous asthma. In syphilitics, he thinks that one should try to avoid only the abuse of tobacco, both as to quantity and quality. In nervous affections, the author again would simply recommend that the amount of smoking be very carefully controlled, the number of cigars and their strength being rigorously prescribed. In cardiac neuroses particularly, the greatest circumspection is to be employed. In gastric neuroses, tobacco should be cut off entirely. Persons who are subject to organic affections of the nervous system can smoke with caution. As for smok-

ing during convalescence, no set of rules are or can be laid down. The author does not take into account, we think, sufficiently the question of age in the matter of smoking. It seems to be pretty well agreed that if a person has reached a fairly good old age as a smoker, he can continue the habit without much injury, even though he be crippled with various chronic disorders, or even if he have a stroke of apoplexy and make from it a reasonably good recovery. On the other hand, permissive advice as to smoking during the first twenty-five years of life is to be given with great caution. Dr. Jankau is a rather lenient sanitarian, and we fancy he is something of a smoker himself.

THE TREATMENT OF ACCIDENTS FROM ELECTRIC SHOCK.

ONE of the contingencies of modern civilization which is almost entirely new, and is wholly dependent upon the development of modern industry, is the treatment of accidents from electric shock. We have had many treatises in the past upon the proper methods of dealing with accidents in drowning, accidents from broken heads, from ruptured blood-vessels, from poisons, and so on, but the art of dealing with electrical accidents is entirely novel. The matter has been discussed quite thoroughly by physicians in this country, but it has been worked out perhaps more systematically by Dr. D'Arsonval, of Paris, who has recently made a report to the Académie de Médecine, of Paris, upon the methods of treating persons injured by electrical shocks. D'Arsonval states that electricity causes death sometimes directly, by the disruptive and electrolytic effects of the charge on the tissues. This death is final. It sometimes, however, causes death indirectly, by arrest of respiration and syncope, caused by stimulation of the nerve-centres. Under these circumstances, a person may be revived, if proper measures are applied. The formula for reviving the victims of electric shock is this: The person so disabled should be treated like one drowned; in other words, he should be laid upon the back, and artificial respiration performed in the way that is ordinarily described. Some further practical advice, however, is given to those who are called at once to the scene of the accident, and at the time when the person is perhaps still in contact with the wires. Of course, the first thing to be done is to stop the current or break the contact. In doing the latter, one should not touch the victim on the face or hands or any naked part of the body. It is better to lift him by the coat-tails, or to throw a blanket over him and pull him by this. Nothing that is wet should be thrown upon him, and if his clothes are wet the hands should not be put in contact with them. A piece of dry wood can be placed under the body, and he can then be lifted. The further treatment of the case is the familiar one applied in attempting to restore the drowned. The arms are worked, and the tongue is kept drawn out; the body may sometimes be rubbed thoroughly with a cloth or brush, in order to increase the circulation of the blood. Oxygen and perhaps a stimulant may be employed.

THE VALUE OF BLOOD EXAMINATIONS AS A TEST FOR MALARIA.

DR. WILLIAM OSLER has recently stated that the diagnosis of malarial fevers can be made with certainty by the blood examination. One further infers that Dr. Osler believes all fevers in which this organism is not found are not malarial. We believe that the weight of evidence supports this view, but it cannot yet be dogmatically taught that the plasmodium of Laveran is surely the cause of the disease.

Of the three forms of evidence necessary to prove that a given disease is caused by a certain specific micro-organism, the history of the plasmodium furnishes at the most only one, viz., it is present in the organism in all cases of the disease, and not in other diseases. The organism has not yet been isolated in pure culture, and its inoculation has not yet reproduced the disease.

There is still scepticism among some competent authorities as to its significance. Recently an East Indian surgeon, Lieutenant-Colonel E. Lawrie, M.B., has written a monograph in which he asserts, as the result of his studies, that this micro-organism is not present regularly in patients suffering from the malarial fevers of India. Naturally, the only argument here is to say that Dr. Lawrie is prejudiced, ignorant, and incompetent; and such answer has been made.

THE PASSING OF THE GARGLE.

THE gargle has been often criticised as ineffective and inefficient, and, theoretically, has been long excluded from rational pharyngeal therapeutics. The *Medical Press*, however, calls attention to the fact that, despite the criticisms upon it, the gargle is still frequently employed, not only in domestic practice, but on the prescription of physicians. The gargle is one of those things which it has been very hard to do away with, because it appeals to the patient, and particularly to the anxious friends and parents, as being something tangible—something that the patient can do. The ability to gargle, also, has been considered one of the milestones in the intellectual and physiological development of childhood, and has, in the parental mind, often been classed with the achievement of walking or the appearance of non-deciduous teeth. There are about the gargle a great many tender reminiscences of juvenile days and tonsillar swelling, and it is somewhat sad to think that all the earnestness and conscientiousness which the rising and risen generations have thrown into the gentle art have been entirely wasted. The musical gurgle of the astringent solutions bubbling in the throat are no longer to be heard, if the general practitioner rises to the high plane to which modern science calls him. The gentle splash of the medicated fluid, after it has performed its supposed healing function, into the cuspidor or basin, will no longer be heard in the land. *Gargarisma fuit*. All this is because physiologists show that the gargle never really goes beyond the posterior pillars, and is, in fact, only a very nasty mouth-wash, which disorders the taste, discolors the teeth, injures the healthy

tissue, and nauseates the palate without ameliorating the pharynx. Mr. Lennox Brown, who writes an epitaph upon the "gargle" as it used to be given, tries to take the pathos from its mortality by saying that there is a form of gargle which may be substituted with some beneficial results. But this particular method, which is that described by Von Troeltsch, is too complicated for any but the trained understanding of the mature and most intelligent classes. It consists in taking a tablespoonful of the medicated solution in the mouth, holding it in the back of the throat, with the head thrown back, closing the nose with the thumb and finger, and making movements of swallowing without letting the liquid go down the throat. Those who have tried this interesting experiment will agree that it is a good deal harder than learning to ride a bicycle, and associated not less often with the disaster that goes with untrained muscles. We do not believe that the Von Troeltsch method will ever be popular. It might as well, therefore, be admitted that the gargle must go, and should, in fact be already long gone.

News of the Week.

The New Photography was commented upon in the editorial columns of our last issue.

Since then Professor Wright, of the Sloane Laboratory at Yale College, has carried out a series of confirmatory experiments which tend to increase the hope we have already expressed that science, and especially medical science, will greatly benefit by this discovery of a way to photograph what cannot be seen.

The very idea of catching and fixing upon a sensitized plate that which the eye cannot perceive, while not a thing beyond the powers of the mind to comprehend, is still so fascinating in its possibilities of utility in medical science that physicians are perhaps more interested than others in the new discovery.

It seems certainly to be established that the shape and location of concealed objects can be reproduced photographically by means of cathode rays, and such foreign bodies as bullets and pieces of glass embedded in the hand have been located, as well as the site of a fracture and pathological change in the deeper tissues. Aluminium seems from Professor Wright's experiments to be a metal which intercepts a smaller proportion of the cathode rays than either brass or platinum. An aluminium medal left so clear an impress upon the plate that it is said the design and lettering upon both sides of it were plainly visible. Professor Trowbridge, of Harvard University, by means of Roentgen's cathode rays, has succeeded in obtaining a photographic effect through wood and pasteboard, and Professor Neusser, of Vienna, has by the same means demonstrated calcareous deposits in the bladder, liver, and kidneys of a live subject.

Moving to New York.—The *Medical Century*, a semi-monthly journal, heretofore published in Chicago, is now published in New York and Chicago. This seems a little like a "straddle," threatening a split, but we wish our contemporary success.

Therapeutics of a Country Doctor.—A country doctor, writing on the above subject in the *Journal of Medicine and Science*, extols the fluid extract of passion flowers as a sedative remedy. It is a drug which is antispasmodic, and it is valuable in tetanus, spasmodic disorders, and sometimes in insomnia. He gives from five to ten drops, repeated frequently.

Epidemic Diphtheria.—Diphtheria is reported to be epidemic in Port Carbon, St. Clair, and Palo Alto, towns suburban to the city of Pottsville, Pa.; and also in Fountain Hill and other towns in Lehigh County.

Suspensio Uteri or Ventro-Fixation of the Uterus—Its Influence upon Pregnancy and Labor.—Dr. Charles P. Noble, of Philadelphia, having recently had some unfortunate experience concerning the influence of suspensio uteri upon parturition, asks for actual results as seen in the practice of different operators who have had cases of pregnancy following suspension of the uterus.

The American Association of Physicians and Surgeons.—The next meeting of the association will be held at Niagara Falls, on June 20, 1896. Dr. C. E. Covey, of Detroit, has been elected *President*; Dr. N. G. Smith, of Indianapolis, *Vice-President*, and Dr. P. M. Kelsey, of Indianapolis, *Secretary*.

Convalescent Hospital for Children.—In addition to the sum of \$20,000 left by the will of Mrs. Anna R. Aspinwall for the founding of a convalescent hospital for children, it appears that the munificent sum of \$3,000,000 has been left in trust to the Hospital of the Protestant Episcopal Church of Philadelphia.

Spurious Dairy Products.—The report of the Pennsylvania Department of Agriculture shows that during the year past an aggressive campaign has been conducted against all dealers in imitation dairy products. Analyses of many samples of food products in accordance with the Pure Food Act of 1895 go to show that adulterations are largely confined to the substitution of lower grades of articles for higher. Rarely has it been found that articles injurious to health are used, and, except in the use of copper for the purpose of coloring pickles, such use might be attributed to accident rather than to design. It was found that salicylic acid was largely employed to prevent fermentation in fruit jams, catsup, etc. Of many samples of buckwheat flour examined, but two proved to be pure, the remainder being adulterated with wheat flour. Three-fifths of the cheese examined proved to be "filled"—that is, the milk had been skimmed, the cream being used for other purposes, and foreign fats (not butter) being added to make up the deficiency. Of the samples of mustard examined, two-thirds proved to be adulterated with common wheat flour colored with turmeric.

Dr. O. W. Braymer has been appointed attending physician to Cooper Hospital, Camden, N. J.

The Berks County (Pa.) Medical Society held its annual meeting and banquet at Reading on January 14th. Dr. Charles W. Bachman was elected president for the ensuing year.

The West Branch Medical Association held its semi-annual meeting at Lock Haven, Pa., on January 14th. The following papers were read: "The Diagnosis of Blood Conditions by Instruments of Precision," by Dr. Judson Daland, of Philadelphia; "The Treatment of Diphtheria," by Dr. Thomas Tobin; "A Review of Some Practical Points in Surgery," by Dr. John A. Klump; "Dysentery," by Dr. A. Hibler; "Hereditary Bleeders," by Dr. Louis Schneider.

The Mescal Button.—Some time ago we referred to a publication regarding the therapeutical use of the Mescal button, by Drs. D. W. Prentiss and F. P. Morgan. These same authors return to the subject in an article in the *Therapeutic Gazette*, of January 15th, and again recommend it as a useful article in nervousness, colic, hysterical manifestations, and as a stimulant in depressed mental conditions. They recommend the use of the tincture, *tinctura Anhalonii*, a ten-per-cent. preparation, dose one to two teaspoonfuls; seven to fifteen grains of the powder may be given.

The Burlington (N. J.) Medical Society held its annual meeting at Mount Holly on January 23d. Dr. J. Howard Pugh, of Burlington, was elected *President*; Dr. Burr McFarland, of Bordentown, *Vice-President*; Dr. Enoch Hollingshead, of Pemberton, *Treasurer*; Dr. A. W. Taylor, of Beverly, *Secretary*.

The Montgomery County (Pa.) Medical Society at its annual session, held on January 22d, elected the following officers for the ensuing year: *President*, Dr. H. F. Slifer, North Wales; *Vice-Presidents*, Dr. J. K. Weaver, Dr. J. C. Spear, Norristown; *Recording Secretary*, Dr. H. H. Whitcomb, Norristown; *Corresponding Secretary*, Dr. J. K. Weaver, Norristown; *Treasurer*, Dr. S. N. Wiley, Norristown.

Hospital for Scarlet Fever and Diphtheria Patients.—Mr. Lexow has introduced a bill in the Senate (New York) authorizing the commissioners of the sinking fund to lease land at the foot of East Sixteenth Street to the hospital for scarlet fever and diphtheria patients.

A New Occupation Disease.—A correspondent of the *British Medical Journal* describes a case of a woman whose profession was that of a straw plaiter. As the result of her work she gradually began to suffer from cramps in the fingers coming on whenever she attempted to do her work.

Mr. T. W. Thorndike has given \$5,000 to the Harvard Medical School to establish a prize fund in memory of his father. A prize of \$200 is to be given annually to the author of the best essay on some subject in any branch of surgery. The students of the Harvard Medical School and graduates of five years' standing of any recognized medical school are eligible for competition.

A Slander Refuted.—A paragraph has lately been given wide circulation in the daily papers charging with unprofessional conduct a prominent physician of Staten Island. It is but common justice to state that

the matter was subsequently brought before the Board of Censors of the Richmond County Medical Society, who reported that, after a searching investigation of all the evidence in the case, the testimony of the accusing side absolutely failed to support the charges, and that the doctor was therefore completely exonerated.

The Massachusetts General Hospital has recently received the bequest of \$20,000 from the estate of the late Martin Brimmer.

A Western Laryngological Society.—A meeting will be held in Kansas City on April 7th, for the purpose of forming an association of physicians in the West who are specially interested in diseases of the nose, throat, and ear.

Contagious Eye Diseases.—A bill before the Senate of South Carolina makes it obligatory on all midwives to report every case of sore eyes in infants, either to the health authorities or to some licensed practitioner.

Manhattan Eye and Ear Hospital of New York.—Dr. William Norris Hubbard has been appointed assistant surgeon to the throat department of the Manhattan Eye and Ear Hospital, New York.

A Legal Lien for Medical Services.—A bill has been introduced by Dr. W. G. Kiger in the Senate of Mississippi proposing that every licensed practitioner of medicine in that State shall have a lien and privilege for medical services on the crop or wages of the person served. While ever ready to uphold the physician in the collection of his just dues, it strikes us that this measure is in the line of class legislation, with the usual one-sided discrimination. How would it work in a retaliatory way on the poor doctor unable to pay his own debts?

Against Drugged Cigarettes.—Mr. Shulum has presented to the New York State Senate a bill making it a misdemeanor to sell adulterated or drugged cigarettes, to sell or give cigarettes to a minor under sixteen years of age, and to provide for the granting of licenses to all venders of cigarettes. A similar bill has been presented in the Assembly by Mr. Mittenacht.

The Late Professor Huxley is said by the spiritualistic journal, *Light*, to have given a communication to Gen. Francis J. Lippitt, of Annapolis. The spirit message was delivered on a slate. Professor Huxley writes: "It is with pleasure I greet you and identify my picture. Let the spirit be ever with you to advance this great work. Yours for the truth, Professor Huxley." While living, Professor Huxley once said that the only good of spiritualism was that it furnished an excellent argument against suicide, for it was far better to live under the most wretched conditions than to die and be made to utter the dismal imbecilities of the spirit message.

Professor Lusk's work on midwifery is to be translated into Arabic for use in the school of medicine at Cairo, Egypt.

In French Surgery hypodermic injections of artificial serum are used to combat the weakness following operations. The serum used is known as "Hayem's," and consists of sodium chloride 5 grammes, sulphate of soda 12 grammes, distilled water 1 litre. This fluid is sterilized by being brought to a boiling point.

A New Operating-Theatre for the Springfield City Hospital.—An addition to the Springfield (Mass.) City Hospital is to be built, at a cost of \$12,000, which is to contain a new and thoroughly equipped operating-theatre.

The New Hospital for Consumptives in Massachusetts.—The commissioners to locate and build the new hospital for consumptives in Massachusetts have decided to locate it in the town of Rutland, Worcester County. Rutland is the highest town in the centre of the State, and is 1,200 feet above the sea level. It is on the line of the Central Massachusetts Railroad, twelve miles from Worcester.

Personal Estates Left by London Medical Men.—The *Medical Press* publishes a list of the sums left by a number of prominent medical men, mostly knights or baronets, who died last year. The estates range in value from nearly half a million to about \$40,000. Sir William Savory, who died at the age of sixty-eight, left an estate worth over £93,000. Dr. John S. Bristowe left an estate worth £15,734, and the late Dr. Tuke an estate of about £30,000. It is estimated that the average of the personal estates of sixty-seven physicians and surgeons whose wills were noticed during six or seven years was £50,614. This is a vastly greater sum than could be credited to a similar number of eminent American physicians, and it is not unlikely that most of these gentlemen inherited, or obtained through some other source than medical practice, the fortunes which they left.

Keats and the Study of Medicine.—In 1818 the poet Keats wrote to his friend Reynolds: "Were I to study physic, or rather medicine, again, I feel that it would not make the least difference in my poetry. When the mind is in its infancy a bias is unavoidably a bias, but when we acquire more strength, the bias becomes no bias." Keats was tempted several times to take up the practice of medicine, but he never did so. He wrote to his brother once: "I have at different times been turning it in my head, whether I should go to Edinburgh and study for a physician. I am afraid I should not take kindly to it. I am sure I could not take fees, and yet I should like to do so. It is not worse than writing poems and hanging them up to be flyblown on the review chambers."

Medical College Statistics.—According to a report of the Bureau of Education for 1893, the number of medical students enrolled in that year was 12,238, and the percentage of the enrolment graduating was 24.9. The percentage of college graduates who study medicine has been declining. There were 132 medical colleges in the United States in 1893. Of these 94 were regular, 16 homeopathic, 10 eclec-

tic, 2 physio-medical, 8 post-graduate, and 2 preparatory. The total enrolment of these was 28,900, and of this number 16,130 were in the regular and 1,445 in the homeopathic schools. There are 36 regular schools that admit women, and there were 1,302 female medical students. The theological schools had 7,856 matriculates and the law schools 6,776 matriculates. The school with the largest number of matriculates was the University of Pennsylvania, the number there being 800. Several other schools have over 600 students. One-fifth of all the medical students, namely, 5,182, are credited to the North Atlantic States, and another fifth to the Central States.

Medical Education in Vienna.—Changes are to be introduced into the methods of medical education at Vienna. The result will be that, from beginning to end, it will take a regular student, of average abilities, seven years or more before he is able to practise.

A New Method of Abdominal Massage.—Kümmerling, of Vienna, describes this method of massage, which he claims to be new: The patient is placed in the right lateral position in order that the descending colon may be manipulated conveniently. The thumb and forefinger of each hand carefully press through the skin and fat till the gut is reached; the finger tips of both hands are then laid over corresponding points of the intestine and powerful "sawing" movements, often causing pain to the patient, are made from above down for about five minutes. He is then placed on the left side, and the procedure repeated from below up upon the cæcum and ascending colon. The massage is finally directed to the transverse colon and small intestine. The patient assumes the knee-elbow position, and the parts are rhythmically kneaded by the finger tips, or, if there is much fat, the closed fists. The whole sitting lasts fifteen minutes, and Kümmerling describes its effect as being extraordinarily superior to that of any other method. The great disadvantages of the abdominal massage in the recumbent posture are the difficulty of gripping the gut in the fingers, and the fact that only its superficial portions are stimulated, peristalsis in the remainder being only obtained reflexly, if at all.

Ladies as Hospital Managers.—A good deal of excitement is said to have been aroused in Edinburgh, by the proposal to nominate a lady for a vacancy on the Board of the Edinburgh Royal Infirmary. There have been some lady members of hospital boards in this city, particularly on the boards of the smaller hospitals. This element does not seem to work very well when it is in the majority, but when it is in the minority it is a useful factor.

Medico-Military Titles.—We have now neither medical directors nor post surgeons in the medical department of our army. The revision of the Army Regulations, issued a few weeks ago, abolished the one, and the first circular of the present year, published from headquarters of the army, January 2d, has done away with the other. The medical officer on the staff of a general commanding a department, an

army, or an army corps, known during the greater part of the past century as a medical director, has now become the chief surgeon of the command, to give uniformity to the titles of the staff functionaries, who are the chief quartermaster, chief commissary, chief paymaster, etc. The recent circular brings the staff of a post commander into uniformity with this system of nomenclature, by directing that hereafter the senior medical officer of a military post will be known officially as the surgeon, and the other officers as the adjutant, the quartermaster, the signal officer, etc.—*Journal of the American Medical Association.*

Preliminary Programme of the Eleventh Annual Meeting of the Association of American Physicians to be held in Washington, D. C., on April 29, 30, and May 1, 1896: "The President's Address," by Dr. A. Jacobi, New York. "The Effect of Acute Alcoholic Intoxication in Diminishing Resistance to Infection—An Experimental Study," by Dr. A. C. Abbott, Philadelphia. "Diphtheria Antitoxin Sometimes Found in the Blood of Horses that have not been Injected with Toxin," by Dr. B. M. Bolton, Philadelphia. "Diphtheria Antitoxin Obtained by Electrolysis," by Dr. B. M. Bolton, Philadelphia, and Dr. H. D. Pease, Philadelphia. "Relation between Endocarditis and Acute Glomerulo-Nephritis," by Dr. W. B. Councilman, Boston. "A Case of Subdiaphragmatic Abscess, Diagnosis, Operation, Subsequent Death from Pleurisy of the other Side," by Dr. E. G. Cutler, Boston. "Clinical and Anatomical Study of So-called Alcoholic Meningitis," by Dr. Charles L. Dana, New York. "On the Treatment of Pernicious Anæmia," by Dr. I. N. Danforth, Chicago. "Study on Streptococci," by Dr. H. C. Ernst, Boston. "Prevalence and Fatality of Pneumonia," by Dr. C. F. Folsom, Boston. "A Case of (Esophageal Hemorrhage with Cirrhosis of the Liver," by Dr. G. M. Garland, Boston. "Syphilitic Nephritis," by Dr. H. A. Lafleur, Montreal. "Wandering Phlebitis (Periphlebitis?); a Case in a Patient Seventy-two Years Old," by Dr. William Northrup, New York. "The Relation of Migraine to Neuralgias of the Fifth Nerve," by Dr. J. J. Putnam, Boston. "Some Points in the Pathology of Gout," by Dr. B. K. Rachford, Cincinnati. "Conditions Influencing the Appearance of Toxin in Cultures of the Bacillus of Diphtheria," "Two Varieties of the Tubercle Bacillus from Mammals," by Dr. Theobald Smith, Boston. "Atrophy of the Spinal Cord," by Dr. M. A. Starr, New York. "A Toxiconic Bacillus found in Ice Cream and its Products," by Dr. V. C. Vaughan and Dr. George D. Perkins, Ann Arbor.

An International Congress of Railway Surgeons is to be held in Brussels in 1897. One of the questions to be debated is this: "Should the Medical Service be a Department of the Management?"

The Extension and Rebuilding of the Charité Hospital, of Berlin, have been begun. It will take ten years to complete the proposed work, and then it is prophesied that the new Charité will be the first of European hospitals.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 3, 1896.

HENRY F. WALKER, M.D., PRESIDENT PRO TEM.

Non-Recurrence of Cancer of Tonsil Three Years After Operation.—DR. CHARLES MCBURNEY presented a patient with the following history: E. W. L.—, physician, aged sixty-three years, first noticed an inflammation of the left tonsil in July, 1892. A constant feeling of discomfort, referred to the tonsil, increased month after month, although careful local treatment was applied by a skilful throat specialist, from the latter part of November on. Iodide of potassium was administered during a period of two weeks. The patient was first seen by me at the end of January, 1893. A portion of tissue removed from the edge of the tonsil had just been examined by Dr. T. M. Prudden, and was pronounced by him to be unmistakably carcinoma. The tonsil at this time was much enlarged in all its diameters. Superficial ulceration of the surface existed, and the mucous membrane of the adjacent portion of the pharynx was cedematous and reddened. Posterior to and below the angle of the jaw, a considerable tumor, the size of a small hen's egg, existed, which evidently consisted of several much enlarged lymphatic glands.

Operation was done on February 1, 1893, with the assistance of Drs. Z. A. Hinson and C. T. Parker.

Preliminary tracheotomy was first made, to facilitate etherization and the subsequent treatment of the wound. A long straight incision, from the lobe of the ear downward and corresponding to the anterior edge of the sterno-cleido-mastoid muscle, was made. Through this a thorough removal of all lymphatic glands and connective tissue was easily accomplished. The external carotid artery was ligated close by its origin. Then a straight incision, about at right angles to the first, was made, passing upward and forward, and crossing the jaw at about the situation of the last molar tooth. The submaxillary gland and all connective tissue and lymphatic glands below the jaw were removed. The jaw was then divided with the saw in the line of the second superficial incision. It was now easy to draw outward the ramus of the jaw, and so completely expose the whole external surface of the tonsil, the large vessels and pneumogastric nerve being drawn backward. The pharynx was then entered with the knife at a point about one-half inch anterior to the edge of the tonsil. The knife was then carried upward well into the soft palate, backward and then downward, always at a considerable distance from the tonsil, until the tonsil, a portion of the posterior edge of the tongue and of the soft palate, and the whole lateral wall of the pharynx were removed.

The divided jaw was sutured with silver wire, and the superficial wound partly closed by suture. The deep wound was packed down to the pharynx with iodoform gauze.

The patient bore the operation well. He was fed for four days by rectal enemata, and then for a week with the stomach tube. On the fifth day, although the use of iodoform had been discontinued, mild symptoms of iodoform poisoning occurred and lasted about a week. After that no incident of moment was noted, and complete healing was reached at the end of a month. When the silver wire was removed, a small piece of necrosed bone came away with it. With the aid of a temporary dental appliance, complete union of the divided jaw took place, and the articulation of the upper and lower teeth was made perfect.

The patient has remained perfectly well ever since then, a period of two years and four months. The specimen which I now show you has been most carefully examined by Dr. T. M. Prudden, and both the tonsil and the large lymphatic glands pronounced to be pure carcinoma.

Non-Recurrence of Sarcoma of Naso-Pharynx Three Years after Operation.—DR. CHARLES MCBURNEY also presented a patient with the following history: T. C.—, sixteen years of age, came under my care on April 27, 1888. In November, 1886, imperfect breathing through the nose was noted, and the left nostril gradually became obstructed. In April profuse hemorrhage from the left nares occurred, and both nostrils became occluded. For seven months there has been some constant bloody discharge, and pain has been severe in the nose, left eye, and ear.

A smooth gray mass fills the left nares anteriorly, and can also be seen with the rhinoscope in the posterior nares.

On April 28, 1888, the left superior maxilla was resected, and a considerable tumor was found to arise from the left side of the body of the sphenoid. This was cut away and the base of attachment cauterized.

The case came under observation again, and recurrence of the disease at the original site was noted. During October a number of cauterizations were made, and on October 22d the original operation was repeated, and a large, soft, polypoid mass was cut away from the body of the sphenoid and the occipital bone. Externally the growth passed outward beneath the malar bone, and was removed from this situation also.

During December, January, and February cauterizations were made, and on February 4, 1889, no evidence of disease remained.

Again, on February 3, 1890, a solid tumor, the size of a walnut, was found in the left cheek. The tumor was movable, and involved neither skin nor mucous membrane.

On February 8, 1890, the original incisions, as for removal of the upper jaw, were again made and the cheek reflected. The tumor in the cheek was removed through incision in the mucous membrane, and was found to extend beneath the malar bone to the zygomatic fossa and to be connected with a considerable polypoid growth in the naso-pharynx. All diseased tissue was cut away and the face incisions sutured. Complete healing occurred before February 25th.

No sign of disease was now noted for six months, when a large soft tumor was found springing from the body of the sphenoid and involving the edge of the left tonsil.

On July 17, 1890, the original incisions were again made, as for removal of upper jaw, preliminary tracheotomy having been performed. The whole growth was removed with scissors and forceps.

Again, on February 24, 1892, a small recurrence at the edge of the palatal opening was removed.

On July 12, 1893, a small point of suspicious tissue was curetted.

On August 16, 1893, the original incisions were again made after preliminary tracheotomy, and recurrent masses were removed with spoon and scissors.

Since the last operation, in August, 1893, no evidence of disease has made its appearance, and the patient has been in robust health. He has a palatal fissure produced by operation, which gives rise to no inconvenience, excepting interference with intonation. During the whole of this period he has been actively employed. The tissue removed at the various operations was examined by Dr. T. M. Prudden, whose reports read: "Gross appearances characteristic of sarcoma. Microscopical examination, spindle-celled fibro-myxosarcoma."

Symptoms Apparently Due to Hepatic Abscess; Piece of Liver Removed, Containing Syphilitic Gumma; Anti-Syphilitic Treatment Followed by Recovery.—

DR. ROBERT ABBE presented a woman, forty years of age, who had first been operated upon in the Woman's Hospital for disease of the Fallopian tubes. Later a rather small ovarian tumor was removed at the same hospital. Following that, she had prolonged hectic condition, with great enlargement of the liver and spleen, emaciation, continuous temperature reaching 103° F. or higher. They suspected abscess of the liver at the Woman's Hospital and made aspiration, but found nothing. A doctor sent her to St. Luke's, with a diagnosis of malignant disease of the liver. Diagrams were shown, representing marked increase in the size of the liver, with subsequent decrease under treatment. When Dr. Abbe saw the patient at St. Luke's, she had the appearance of one suffering from abscess of the liver. There was bulging laterally in the region of the liver, and in the median line nearly to the umbilicus, which was supposed to be due to enlargement of the liver alone; but at operation the spleen also was found enlarged, so that the two organs met and formed a continuous tumor. The temperature was above 102° F., there was hectic and emaciation. Dr. Abbe aspirated, expecting to find pus in the liver, but found none. He then concluded there was a deep abscess which could not be reached easily by the needle, and proposed laparotomy which the patient accepted. After opening the abdomen, he punctured the liver in various directions, but obtained no pus. Besides revealing enlargement of the spleen as well as of the liver, the operation brought to view multiple gummata of the liver, varying in size from a bean to a walnut. One or two were at the free edge; some were elevated one-third their thickness above the surface of the liver. They were of grayish, almost malignant appearance, but there were two excavated scars, which showed immediately that they could not be malignant, and subsequent microscopic examination and treatment confirmed his supposition that they were gummata. After taking out a wedge-shaped piece of the liver, about one inch by one inch and a half, including one of the gummata, he closed the wound. There was no hemorrhage. After the operation the patient was treated freely by mercurial inunctions for about two weeks, until the gums were touched; then iodide was given. She made a perfect convalescence, the temperature soon returning to normal, the liver and spleen decreasing in size, flesh and strength returning, and to-day she is in perfect health. The case was one of typical hyperplasia with gummata of the liver, in a patient from whom no history whatever of syphilis could be obtained.

Perforating Ulcer of Stomach; Operation; Recovery.—DR. R. F. WEIR said that, having had two cases of failure from operation for perforation of the stomach, he now took pleasure in presenting a successful case. In this instance the operation was done eleven hours after the occurrence of perforation; in one of the others, four days subsequently; and in the other, forty-eight hours afterward.

The patient presented was a girl, sixteen years of age, who had had a history of gastric disturbance for some months. On December 18, 1895, she was seized with violent pain in the left hypochondrium, and being attended by one of the most intelligent ex-house surgeons, the nature of her trouble was recognized, and he transferred her at once to Dr. Weir's hospital service. As stated, he opened the abdomen eleven hours after the first symptom of perforation became manifest, found slight adhesions between the anterior wall of the stomach and liver, and on separating these a perforation of the anterior wall of the

stomach, one-fourth of an inch in diameter, came into view. This was promptly closed by two or three stitches. Some difficulty was experienced in keeping back the contents of the stomach, but by careful use of sponge and pad, leakage was prevented from extending any distance. These stitches were supplemented by two layers of Lembert sutures. Surrounding about one-half the ulcer was a thickened mass in the wall of the stomach, about two inches in diameter. There was some doubt whether this was purely inflammatory or whether it was tuberculous, for the girl had given some signs of tuberculosis in the lungs. One case had been reported where a second ulcer had perforated during the course of treatment of the first and had produced a fatal result. This fact had caused him some anxiety in the present instance, but the patient had an easy convalescence and was now quite well. She was fed a few days by rectum, then was allowed food without residuum, and a few days later was given solid food.

At the time Dr. Weir had reported his first case, 1891, only about four others were on record, of which only one had recovered. Since then he had collected about forty cases, most of them in England, some in this country. There had been fourteen recoveries. They showed great necessity for early operation. Among successful cases it was done latest in his own case, after eleven hours. Later investigation had corroborated the facts set forth in his paper of 1891, that ulceration causing perforation of the stomach occurred most frequently on the anterior wall. Ulcers themselves formed more frequently on the posterior wall, but for anatomical reasons—adhesions to the liver, etc.—they were less likely to result in open perforation. Sometimes a large quantity of fluid accumulated behind the stomach in these cases, and might be mistaken for empyema of the chest by medical men. There was less likelihood of its travelling and simulating appendicitis than in abscess of the gall bladder, although, in one of Dr. Weir's cases, the patient had severe pain in the region of the appendix, appendicitis was suspected, and an incision was made, but the appendix itself was found healthy; the abscess extended upward and was traced to a minute perforation of the stomach. Regarding the subsequent history of patients recovering from perforation of the stomach, Bolling had found in those observed from six weeks to three years no further trouble referred to the stomach. In reply to a question, Dr. Weir said the patient presented was not in collapse.

Acute Cholæmia in Obstructive Jaundice Produced by Impacted Gall Stones.—DR. KINNIEUTT reported this case. The patient was admitted to his ward with the history of a characteristic attack of biliary colic six days before, of several hours' duration, and relieved only by morphine. There had been no return of pain, but the patient had become deeply jaundiced, and there had been continuous fever. On admission, the jaundice was intense, the temperature was 105.6° F. (mouth), and there was slight mental disturbance. There was a copious erythematous eruption, with urticarial wheals of the neck, chest, and upper extremities. The liver was markedly enlarged (edge two inches below costal arch in mammillary line), the gall bladder was not palpable. The patient became acutely delirious on the second day after admission. On the fourth day, there was a single attack of unilateral spasm of a few moments' duration, with loss of consciousness. The temperature range was from 101° F. morning, to 105° F. evening, the delirium alternated with more or less marked stupor, the signs of obstructive jaundice increased, if possible; the white stools indicated that no bile was passing into the intestines. On the fifth day surgical interference was advised, and on opening the abdomen the common duct

was found dilated to the size of the thumb; two calculi, 1.56 cm. and 1.57 cm. respectively in diameter, were removed, and a third was felt, but pushed into the intestine. The liver was enlarged, the gall bladder not distended. The patient's mental condition did not improve perceptibly after operation; the stupor and delirium persisted, and she died in coma on the third day following operation. The symptoms were apparently those of acute cholamiae as the result of obstructive jaundice. Albumin and casts were present in the urine, but not to a greater degree than is common in obstructive jaundice, and there was no history of antecedent renal disease.

The case is of interest in several respects, and especially in view of the presence of acute cholamiae, which is of rare occurrence in obstructive jaundice.

Discussion on the Several Cases.—DR. WEIR thought Dr. McBurney's first case, naso-pharyngeal sarcoma, illustrated two important points. First, that the spindle-cell tumors were much more amenable to treatment, a fact corroborated by other observers. He recalled that Dr. Sands had had a case which was cured after repeated operations, and the speaker himself had had one which was controlled after three or four recurrences. The second point had already been alluded to by Dr. McBurney, namely, the great advantage of taking away a portion of the upper jaw, thus allowing ready access to the tumor in case of recurrence.

The result in the second case, that of sarcoma of the tonsil, with enlargement of the glands of the neck, was most satisfactory, for such cases were among the most serious of all those encountered by the surgeon, and when a case was cured he deserved the highest praise for the thoroughness with which he had done the operation. The method which had been employed was similar to that of Mikulicz, which afforded best access to the parts immediately involved and to the glands under the sterno-mastoid muscle.

The Galvano-Cautery Wire in Sarcoma of the Nares.—DR. BEVERLY ROBINSON raised the question of the advisability of using the galvano-cautery wire in cases of sarcoma of the nasal passages. Some gentlemen in the city, with a certain amount of throat experience, had gained considerable notoriety from the use of the galvano-cautery snare in the treatment of naso-pharyngeal sarcoma when first seen. Was it desirable that patients should be operated upon in that manner? Naturally one would feel at first that it was more agreeable than to have the jaw removed and everything exposed, but would it be to the ultimate advantage of the patient? Inasmuch as it was likely the patient would in any case finally reach the surgeon, would it not be better to teach the profession to have the cases operated upon in a radical way in the first instance?

DR. ABBE said that about four years ago his attention had been called especially to these tumors, although he had operated on one or two cases prior to that date. He remembered that at a meeting of a medical society in Boston, Dr. Cheevy had presented a patient operated upon by him for sarcoma of the naso-pharynx ten years before, and three or four times later for recurrences, the patient being finally cured. These growths seemed to appear about the time of puberty, and to grow actively for three or four years, and if they were attacked boldly they tended to die out. At least, Dr. Cheevy called attention to that fact and quoted some German authority. An illustrative case was one of fibro-sarcomatous type, with excess of angiomatous structure, in which Dr. Abbe had removed the tumor about three years ago, and in which he and Dr. Delavan employed the galvano-cautery needle to keep the growth under control subsequently. The patient was at present in perfect health, except for a slight recurrence of the growth, which was being held

in check. Lately Dr. Coley had subjected him to toxin treatment, with the result that after each injection the face became so swollen and he suffered so great distress that he refused to have it continued. Dr. Abbe was under the impression that the condition of the tumor had remained the same. The fact should never be lost sight of, that early in life such sarcomatous growths could, by repeated attacks, be ultimately cured.

DR. MCBURNEY said he had operated in another case of naso-pharyngeal sarcoma in a young man, about twenty years of age, over five years ago. The first operation was begun by removing a part of the upper jaw. Second and third operations were performed at intervals, and it was now over five years since there had been recurrence.

He was a very strong believer in thorough and persistent operating on cases of malignant disease. He believed with Dr. Weir that the cases related belonged to a favorable class, but it was desirable, in view of the little confidence which could be placed in other modes of treatment, to call attention to what could be accomplished by actual work. The great objection to certain seemingly plausible methods, but whose value had not been proven, was that they led the profession away from methods which had stood the test of time and had given satisfactory results. In saying this, he did not mean to express the opinion that there had been no improvements upon old methods, but simply that we ought to resist the application of untried methods to the exclusion of old ones which had given good results. So far as concerned the use of snares, he could wish all snares destroyed before being applied to malignant tumors. They were wrong in mechanism and wrong in practice, and to use them was to ignore the whole pathology of the disease. It was utterly impossible to apply a snare to a malignant tumor, except in some extraordinary case, in such a manner as to remove the disease. It was about as impossible as it was to destroy malignant disease by caustic paste.

DR. WEIR.—The use of the snare is a snare?

DR. MCBURNEY.—I think so—and a delusion.

DR. WEIR did not wish his former remarks to be applied to that other class of sarcoma of the naso-pharynx, which were among the most dangerous to operate upon and in which recurrence was very likely to take place.

DR. BRYANT said he began to cultivate his acquaintance with sarcoma of the naso-pharynx by treating a case with the snare in 1887 or 1889. He snared it vigorously, but it bled more vigorously and grew rapidly. He then tried the hot needle. Finally he made up his mind to remove it, and as a preparatory step tied both external carotids. Then, on cutting into the tumor, he was struck by its anæmic condition, induced by ligation of the vessels, and it occurred to him to let it alone and observe what would be the result of cutting off the circulation. He watched the case three years, and two years ago, when he last saw the patient, the tumor had become reduced to about one-third its original size, was tough, fibrous, entirely inactive, and caused the patient no trouble. Within two or three weeks he had received a reprint of a case so treated by Dr. Dawbarn, with a similar result. It was a question whether these growths did not tend to disappear after a certain time, and cutting off the circulation simply held them in check until that period arrived. He was certain that operations on naso-pharyngeal growths was very much facilitated by ligation of the vessels and by removal of the jaw.

Gummatous Tumors and Fever.—DR. BEVERLY ROBINSON, referring to Dr. Abbe's case, in which there were continuous fever and gummatous tumors not broken down, said he had asked Dr. R. W. Taylor to examine one of his patients supposed to be suffering

from either gumma or malignant tumor of the left lung, and Dr. Taylor had expressed the opinion that it was malignant disease, for the reason that there were continuous fever and absence apparently of breaking down of the tumor.

DR. PEABODY thought the case was extremely interesting from certain points of view. First, it illustrated very well the existence of unconscious syphilization, for the woman had no motive for denying it, while she had every reason for revealing it had she known of its existence. Again, it illustrated very well the impossibility, in this instance, of correct diagnosis and treatment without surgery. The surgery did not cure the patient, but it made diagnosis possible, which led to right treatment and cure.

DR. ABEE added that this case was another which went to show that to-day it was possible to remove tumors of the liver with no harm to the patient. Indeed, it was safer to attack this organ than almost any other. Out of twenty cases collected by Keen two years ago, there was but one death. In animals as much as three-fourths of the liver could be removed and recovery follow, with subsequent compensatory hypertrophy of the remaining portion.

DR. MCBURNEY thought Dr. Weir's case of perforation of the stomach emphasized the grave responsibility which rested upon the person who first saw such cases. This was true, not alone of the stomach, but also of the intestine and any viscus. Of course, we could not form an opinion of the rapidity with which pathological changes took place after perforation, but all were familiar with the fact that for a period, say a few hours, there were almost no changes even in cases of one or several perforations of the intestine. The peritoneum during this period looked perfectly normal, and one could scoop out escaped feces and yet see the case go on to good recovery under proper and timely treatment. After this period, however, the pathological changes developed with frightful rapidity. In perforating appendicitis, for example, it was incredible how soon, following a certain period, the belly became filled with nasty, fetid material. What the surgeon desired was to operate within that limited time, and the case of Dr. Weir's was an example of the happy results which followed. In ninety-nine cases out of a hundred, fatalities were due to delay in operation.

DR. KINNICUTT reported a case of recent occurrence in his wards, in which a successful operation was performed, probably as late as three weeks after perforation. The patient was admitted suffering from obscure gastric symptoms. There was no history of acute epigastric pain at any period, of hæmatemesis, or, in fact of any gastric symptoms, other than a moderate degree of discomfort. There was, however, evidence of a very localized peritonitis in the upper umbilical region; there was also a slight, irregular, but continuous rise of temperature. The right lobe of the liver was not enlarged; it was impossible to determine the lower limit of the left lobe, on account of the sensitiveness to palpation and the rigidity of the recti muscles. As the signs of a localized peritonitis continued, the diagnosis was believed to lie between a perforating gastric ulcer and an abscess of the left lobe of the liver. An exploratory incision was performed by his surgical colleague, Dr. McCosh, and a small abscess was found, communicating with a perforating ulcer of the anterior wall of the stomach, near the lesser curvature, about three-fourths of an inch in diameter. The abscess was entirely shut off from the general peritoneal cavity by adhesions between the anterior wall and the under surface of the liver, and by a large amount of inflammatory exudation. Secure limitations in cases of perforating ulcer of the anterior wall were extremely rare, though comparatively common in

perforating ulcers of the posterior wall. The patient had made a perfect recovery.

DR. KINNICUTT, in reply to Dr. Weir, said that the case related by him differed from those just referred to by Dr. Weir, in that the perforation was of the anterior wall, where adhesions were of very rare occurrence.

DR. W. M. POLK supposed Dr. Weir's case belonged to the class of acute perforating ulcer of the stomach, while Dr. Kinnicutt's belonged to that class in which the process of perforation was very slow, giving ample time for adhesions to take place. The one class was always preceded by a very distinct set of symptoms, so that the condition could be fairly diagnosticated, while the other was not always so readily recognized by the antecedent history. He therefore presumed Dr. Kinnicutt would not have the inference drawn that late operation would prove as successful in Dr. Weir's case as in his own. Certainly, in acute perforating ulcer of the stomach, delay, according to his personal experience, was most disastrous. He had had two cases; both patients were in extremis and died. In one he was much struck by the fact that the perforation, which was upon the anterior wall of the stomach, was not accompanied by general peritonitis, and the patient died of shock from the initial extravasation. The peritoneum was quite free from exudate. The other case presented a condition not unlike that of Dr. Weir's, except that the perforation was larger. Cases like Dr. Kinnicutt's gave abundant warning; one could select his time for operating and follow the course usually adopted in cases of chronic abscess of the peritoneum.

DR. KINNICUTT said that the inference suggested by Dr. Polk was the last that was intended by him. The delay in operating was necessitated by the great obscurity of the symptoms. If a diagnosis of perforation could have been made with any certainty, surgical interference would have been advised at the earliest possible moment.

DR. POLK.—I beg pardon, and take back all I said.

Peritonitis Caused by Non-Perforating Ulcer of the Stomach.—DR. ROBINSON mentioned a patient who died in his wards eight hours after admission. The case was seen by his house physician and surgeon, not by himself, and their diagnosis was that of miliary tuberculosis. Dr. Thacher made the autopsy, and found two ulcers of the stomach beneath the liver (without distinct perforation into the abdomen), and peritonitis which he attributed to the ulcers. Dr. Thacher stated that ulcer of the stomach was quite capable of giving rise to peritonitis when one could find no opening into the abdominal cavity.

DR. ABEE thought these cases should not be regarded as necessarily hopeless, even though there were extensive extravasation, provided there were also a limiting peritonitis. He recalled one with large extravasation over the liver and under the diaphragm, in which the patient recovered from the abdominal condition, but died on the eighteenth day from pneumo-thorax and secondary abscess which had worked its way up from behind. It was an example of that class of cases in which liver dulness was replaced by tympanitic resonance due to gas escaping from a perforative ulcer of the stomach.

DR. WEIR said Dr. Kinnicutt's case belonged to another class than those of the acute form, being grouped under the slowly progressive or chronic form. In acute perforation the point made by Dr. McBurney was an important one, namely, early operation. In one case which had been reported the belly was opened at the seventh hour, yet that early it was full of turbid serum from commencing peritonitis. The question of peritonitis depended upon the quantity and virulence of the matters extravasated. In a case which had come

under his observation, but not under his care, the abdomen was opened the sixth hour after perforation of the sigmoid flexure, and was then found to contain nearly a pint of turbid pus.

The majority of cases collected by Dr. Weir had given a history of some gastric trouble, and fully one-third of them had recently partaken of a hearty meal which had caused agonizing pain. These facts taken together should give some clue to diagnosis and early operation.

DR. KINNICUTT remarked that the interesting feature of his case was that the perforation was not of the posterior, but of the anterior wall of the stomach, and yet adhesions had formed which prevented escape of fluids into the general cavity.

DR. WEIR remarked that this was very unusual, yet such cases had been reported.

Report of Case of Supposed Abscess of Liver; Laparotomy; Excision of Piece of Liver, with Relief of Symptoms and Complete Recovery.—DR. GEORGE L. PEABODY read the paper (see p. 193).

DR. POLK could recall two or more cases of multiple abscess of the liver, varying in size from the end of one's thumb down, clearly traceable to inflammation extending from stones in the gall bladder, there having been, however, no history of biliary colic or of the passage of stones, and no jaundice prior to the suppurative process, say a month before operation. The history was rather of that form of malaria which exists in the suburbs of New York.

Regarding the favorable result of operation in Dr. Peabody's case, it would be recalled that some years ago a gentleman gained some reputation in this city for cure of liver trouble by repeated tapping of the liver, a method employed in some parts of India and elsewhere. The needle was introduced into the liver without laparotomy.

DR. PEABODY believed fevers connected with various hepatic troubles, including abscess, were often mistaken for malaria. If in his case gall stones and supuration of the gall bladder had been the cause of the multiple abscesses, the patient would not have been cured, but the condition would have progressed.

DR. ABBE inquired whether there was any history of syphilis in Dr. Peabody's case, for the cells described were very much like those seen in gummata.

DR. PEABODY replied that there was no history of syphilis, and the patient had recovered and remained well without any specific treatment.

The Cyclo-Ambulance.—A German surgeon, Dr. Hoenig, has designed an apparatus which he calls a cyclo-ambulance (*The British Medical Journal*). It consists of a car covered in with canvas, which contains a folding litter and rests on four side-wheels, and a fifth wheel in front pedaled by a cyclist. A seat and pedals are also provided at the back for another cyclist. The top part of the car can be lifted off, a patient can then be placed on the litter, and the top replaced on the axles. The patient can be watched by the cyclist at the back through a glazed window; but the patient is also provided with the means of attracting the attention of the cyclist by using the rubber ball of a cycle horn. An aperture in the side of the car affords access to the patient when he is in need of help. The ambulance is reported to be in experimental use in Berlin, and is easily steered and manipulated.

A Pleasant Treatment.—A physician in Illinois treats his cases of erysipelas with external applications of honey. In erysipelas of the face, it is said to quickly relieve the pain and greatly shorten the attack.—*National Medical Review*.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 27, 1896.

DR. EDWARD D. FISHER, PRESIDENT, IN THE CHAIR.

Report of Committee on Hygiene.—DR. JOHN WINTERS BRANNAN, the chairman of the committee on hygiene, reported that since the appointment of the committee last November, several measures of importance to the public health have received their attention. The first of these was the pernicious custom of harboring vagrants and homeless men in the city police stations at night. This practice will probably shortly be abandoned, and the system now successfully employed in Boston substituted. Lodging-houses have been established there, where deserving men who apply for shelter are assisted in finding employment, while common vagrants are sent to the workhouse. Dr. Brannan next referred to the filthy habit many people have of expectorating in public places. This practice is not only filthy, but a menace to the public health, and with the aid of the Health Department steps have already been taken to abate it. Notices are to be posted in public conveyances, buildings, etc., calling attention to the danger of free expectoration, and proper receptacles are to be provided by the officers of transportation lines. Later on it is hoped that these measures will be followed by a prohibitory law on this subject, similar to that existing in Paris. The third point touched upon by Dr. Brannan was the establishment of separate hospitals for consumptives. One of the buildings on Blackwell's Island will be set aside for this purpose, and it is expected that the transfer of the city insane to the State asylums will furnish further accommodation for tuberculous patients.

Significance of Pleurisy, and Some Points in Its Treatment.—By DR. EGBERT LE FEVRE (see page 181).

DR. R. C. M. PAGE said the idea that a pleurisy, whether acute, subacute, or chronic in character, is generally, if not always, of tuberculous origin, was first brought to his notice early in 1888. The following August, while in Paris, he visited Landouzy, the original advocate of this theory, who forcibly reaffirmed its correctness, and whose investigations on the subject certainly seemed very conclusive. In London, however, it was just as conclusively shown that this theory does not hold good there, nor does it in this city. Cases of acute pleurisy have come under his observation which ended in complete recovery, and now, after from five to seven years have elapsed, the patients have no symptoms of tuberculosis. It is no doubt possible that the damage done by an attack of pleurisy may render the subject a more favorable one for tuberculous infection. The late Dr. Flint held that a double pleurisy with effusion was always of tuberculous origin; Dr. Page said he did not think this was always the case, although he believed that most chronic pleuritis are tuberculous.

As regards treatment, sodium salicylate is undoubtedly the proper remedy to employ in rheumatic cases. In other types of the disease it may do harm by depressing the heart. To counteract this, he usually gives tincture of digitalis at the same time. Aspiration of the chest should always be regarded as a very serious operation. Especially in acute pleurisy with effusion, there is danger of producing adhesions in the withdrawal of the fluid by bringing the inflamed layers of pleura together. To counteract this, he usually advises hill climbing, the pneumatic cabinet, or pulmonary gymnastics.

DR. BEVERLY ROBINSON said he did not think that

thoracocentesis in pleurisy should be regarded in any sense as a dangerous operation. On the contrary, he considers it a very innocent one. He has advocated and practised it for many years, and he has yet to see a case in which any subsequent evil results could properly be attributed to it. He expressed the view that, whenever a notable quantity of fluid is present in the chest, it is proper, it is judicious, it is in fact almost imperative to remove it by aspiration. He does not think it good treatment to wait for the production of a large amount of fluid.

Regarding the proportion of tuberculous and non-tuberculous pleurisy, the speaker thought this varied according to the class of patients we have to deal with. In the City Hospital, for instance, we are apt to see many more cases of tuberculous pleurisy than we do in private practice or in hospitals which have a good class of patients.

DR. CHARLES E. QUIMBY said he did not agree with the statement made by Dr. LeFevre that the withdrawal of the fluid in tuberculous cases is frequently followed by a rapid extension of the tuberculous process. If the fluid is removed and the nutrition of the lung neglected, the patient will very likely do badly, but if the nutrition of the lung is properly looked after by stimulating the circulation, by expanding the lungs, etc., the diseased area is put in better condition and in a large majority of cases the result will be beneficial to the patient.

DR. LE FEVRE then closed the discussion.

The Position of the Patient During Parturition, with Special Reference to the Merits of the Walcher Position.—DR. ANDREW F. CURRIER read a paper on this subject. He stated that in the practice of obstetrics in this country we have become so accustomed to the dorsal position of the patient during the second and third stages of labor that the question is seldom asked, by the average obstetrician at least, whether there is any position which is more advantageous for either parturient or accoucheur. In those cases in which operative interference becomes necessary, we are accustomed to make use of the lithotomy position, which, while it fixes the pelvis and gives us a basis of support, also diminishes the antero-posterior diameter of the pelvic brim, and hence must theoretically increase the difficulties of delivery. Practically, it seldom does.

The position with which the dorsal comes most into competition is the left lateral, sometimes called the English position, which is spoken of with great favor by many of our most experienced obstetricians. It is chiefly applicable for normal, that is, non-instrumental deliveries. The only advantages which are claimed for the English position are that the sensibilities of the patient are spared by the non-exposure or supposed non-exposure of her person during delivery, she is spared the annoyance of being moved about before and after delivery, and it is said the perineum can be better protected against rupture. In regard to the first of these so-called advantages, it is possible to deliver in the dorsal position without exposure, and as to the second, a change to the dorsal position becomes almost imperative if any reparative operations upon the vagina or uterus are indicated after labor is completed. The perineum can be protected in the dorsal as well as in the lateral position. The speaker said that personally he preferred to deliver always in the dorsal position unless some objection to it is offered by the patient.

Dr. Currier then called attention to the mobility of the pelvic joints during parturition, and the value of extension in lengthening the antero-posterior diameter and rendering the pelvis as roomy as possible. The value of this principle of extension was recently brought to the attention of the profession by Walcher,

more especially as an expedient which would obviate the necessity of symphyseotomy in cases in which that operation would otherwise be called into use. Walcher's thesis in regard to the position of extension was made in 1889,¹ and was that the conjugate of a narrow pelvis was not a constant quantity, but might vary according to the position of the woman. If a woman were placed in the dorsal position, the legs flexed on the thighs and the latter on the body, the body being somewhat elevated, the promontory of the sacrum may be readily reached by the finger in the vagina. In that position the *conjugata diagonalis*, according to different observers, measures from 9.7 to 10.4 centimetres; if now a pillow be laid under the sacrum and the legs allowed to hang downward over the edge of the bed or table, as far as possible, the promontory may be felt receding as the knees drop, and the conjugate will then measure from 10.5 to 11.6 centimetres. A gain of one centimetre may therefore be obtained in the antero-posterior diameter between extreme flexion and extreme extension; it is sometimes less and it is sometimes much more.

Aside from Walcher himself, many observers have obtained excellent results by employing this method. The following are the indications for the use of the Walcher position, and the objections to it. It is indicated in—

1. Cases of protracted labor in which the dimensions of the pelvis are normal or the antero-posterior diameter is somewhat shortened, the head being above the brim. The patient being placed in the position of extreme extension for an hour or more, the pelvic joints may become so relaxed or the antero-posterior diameter lengthened by the necessary half-inch, that the head will engage and labor be terminated normally or with forceps. The high forceps operation, version, or symphyseotomy are thus avoided.

2. Cases in which version, either cephalic or podalic, has been performed, or footling or breech cases. The flat pelvis, the generally contracted pelvis, transverse positions, and occipito-posterior positions are in this category.

3. Cases in which some form of operative procedure has already been adopted without success. It has thus far been used after high forceps operations, version, symphyseotomy, craniotomy, and low forceps, and it will probably be shown to have a still more extensive field.

The length of time during which the position may be used to advantage depends upon the effect which it produces upon the patient. It has been shown by those who have used it that it may be discontinued and re-employed without disadvantage and sometimes with positive advantage. After the legs have been suspended half an hour or an hour, it would usually be desirable to discontinue the position for a time, since it is tedious and may cause interference in the venous circulation of the legs and thighs. After a rest of an hour it can be resumed, if necessary.

In conclusion, the speaker said that the contribution of Walcher to practical obstetrics is certainly a valuable one, and will often prove as useful as it is simple and harmless.

DR. S. MARX said that those who have been in the habit of delivering women from the side will not give it up for the dorsal position. Our modern beds are so constructed that when we attempt to deliver on the back the underlying perineum is usually deeply embedded in the mattress. The speaker said that if the statistics we get from Europe are true, the Walcher position in difficult cases of labor is of immense value, and he expressed the hope that it would relegate that barbarous operation, symphyseotomy, to the obscurity it deserves. In the Walcher position, the

¹ Centr. f. Gyn., 1889, li., p. 892.

gain in the pelvic measurements is obtained by the action of the ileo-femoral and anterior accessory ligaments; these prevent the sacrum from moving forward, but do not prevent it from moving backward. In one case coming under his observation, where he had been unable to deliver with the Tarnier forceps, delivery was accomplished without difficulty by putting the woman in the exaggerated Walcher position. This method is not applicable to cases of flat pelvis, nor where there is ankylosis of one or the other sacro-iliac synchondrosis, and it should be at once discontinued after the head has passed the obstruction. Another objection to it is that in private practice the beds are usually so low that it is almost impossible to put a woman into the exaggerated Walcher position.

DR. JULIUS ROSENBERG expressed the opinion that if the Walcher method is practised with the same enthusiasm as symphyseotomy has been, the cases in which the latter operation is called for will probably largely decrease, as the gain in the pelvic measurements is almost as great in the former as in the latter.

DR. CHARLES A. KINCH continued the discussion, which was then closed by Dr. Currier.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, January 23, 1896.

W. R. PRYOR, M.D., CHAIRMAN.

Election of Officers.—In the absence of the chairman, Dr. Coe, Dr. H. L. Collyer called the meeting to order, and the section proceeded to the election of a chairman and secretary for the ensuing year. Dr. W. R. Pryor was elected chairman, Dr. S. Marx secretary. Dr. Pryor then took the chair.

Embryonic Specimen of Twins.—DR. MARX presented an embryonic specimen, representing twins aborted at the twenty-eighth day. He knew of no other similar specimen at so early a period.

Ectopic Gestation; Two Specimens.—DR. MARX also presented specimens of ectopic gestation from two cases, one removed through the vagina, the other by the combined method. The cases illustrated the difficulty of diagnosis and the advisability of vaginal operation, which certainly gave an ideal convalescence. The first patient had recently contracted gonorrhœa from her husband, had irregular bleeding for three weeks, and he and Dr. Grandin were uncertain as to the nature of a tumor which developed at the side of the uterus, but were disposed to think it was a gonorrhœal abscess. The abscess was cut into easily from the direction of the vagina, but the tumor slipped up and was reached by the suprapubic opening. It was found that the abscess occupied the uterine end of the tube, while the chorionic villi were in the extreme outer or fimbriated end. The woman went home in ten days. In the second case the diagnosis was based on irregular hemorrhage of four weeks, while no distinct tumor nor other pretended characteristic signs of extra-uterine pregnancy was present. On opening from below, an enormous quantity of clotted blood gushed out, showing that internal hemorrhage must have been going on a week or longer, yet the pulse was only 68, and the patient's condition good. A large vessel was injured, and not being able to tie it from below, Dr. Grandin, who was assisting him, rapidly made a suprapubic opening and controlled it. The patient recovered.

Double Dermoid Cyst.—DR. H. J. GARRIGUES presented two dermoids, one from each ovary. The smaller ovary was composed of two parts, one containing the dermoid cyst, the other a corpus luteum in

which there was a central cyst. The case was interesting from a diagnostic standpoint, for the physician had sent the patient to him with the diagnosis of extra-uterine pregnancy, and on careful examination Dr. Garrigues did not doubt its correctness. On operating he found uterine gestation and the two dermoids. The uterus had given him the impression of being small, but that was explained later by the fact that he felt only a small part of it, the remainder being covered by the larger cyst. The smaller cyst was behind the uterus and was not felt. He did not doubt the diagnosis, because he could feel what seemed to be the pelvic end of the foetus, but this was found to be two bones in the dermoid pointing that way. The case also illustrated the best treatment for abortion, namely, to empty the uterus entirely.

DR. H. N. VINEBERG, referring to Dr. Marx's case, wished again to warn against placing too much stress on any one sign of extra-uterine pregnancy, whether irregular hemorrhage, colicky pain, or other sign. Patients should not be allowed to get up after vaginal work before three weeks.

Symphyseotomy, its After-Effects, with a Description of a New Method.—DR. EDWARD A. AYERS read the paper. He first related four cases in which he had operated. 1. Mrs. B—, first child delivered stillborn by forceps. Seen by him in December 1894; twenty-four hours in labor, right shoulder presenting, dorsum anterior. After careful efforts with forceps, symphyseotomy was performed, separation of one inch, but the pulse ceasing in the cord, delivery was completed by craniotomy. *Conjugata vera*, three and one-third inches. Recovery most satisfactory. 2. Mrs. R—, March, 1895; conjugate, three and one-eighth inches, separation obtained of two and one-fourth inches; foetal heart heard two minutes before delivery with forceps. Male child, over nine pounds, born dead. Recovery of mother most satisfactory. In these two cases podalic version would in his opinion have been better than forceps. 3. Operation, December 12, 1895; pendulous abdomen, funnel-shaped, generally contracted pelvis, chief contraction in transverse diameter; separation of two and one-half inches ensued; delivery of twins, one male, the other female; biparietal diameter of each, four and one-half inches. This case was unique, being the only instance in which twins had lived. Mother and babes were presented. 4. Recent case, woman three days in labor, *conjugata vera* three inches; separation obtained of two inches and one-eighth during forceps delivery. Child weighed seven pounds, and is in fine condition to-day. Mother's recovery uneventful.

Method of Operating.—The method employed in all four of the cases was as follows: Patient at edge of the table, thighs flexed, small male urethral sound introduced to hold the urethra and turn the bladder to the left. Labia minora and clitoris drawn well up to the patient's left, operator's left index-finger introduced into the vagina, pressed against the posterior curve of the symphysis up to the top of the joint; small incision made about half an inch below the clitoris, curved probe-pointed bistoury passed through the wound close against the joint, and up until it could be felt by the index-finger in the vagina above. The pubic bones being V-shaped in front, it was easier to follow the line of union than from behind. With due care, no vessels of importance would be severed. The blade of the bistoury was now carefully worked down through the symphysis, the left index-finger still acting as a guide, and keeping the urethra and bladder out of the way. A small scalpel would be better than the curved bistoury, at least at the commencement, but the blunt point of the bistoury was a safeguard against injury to the subcutaneous structures and finger above. There was no comparison between this method and

Morisani's and Pinard's. In none of the four cases was there hemorrhage of moment.

The after-treatment consisted in the use of iodoform gauze, plaster strips around the hips, gauze removed in thirty-six hours, vulva and vagina kept clean by bichloride irrigation; catheterization could be done without risk; in no case was it employed more than twice. Any plastic operation should be postponed.

DR. AYERS used the term new method by contrast with Morisani's and Pinard's, which were the only ones given in text-books. He claimed no special originality, as suggestions had been received from different sources, the general operation having been suggested by Dr. Dawbarn.

After-Effects.—The joints in all four of the patients were satisfactory and showed firm union, and this was true of all the cases operated upon in this country so far as he had been able to learn, and he had heard from a large number. It appeared, therefore, that there was a natural tendency for the parts to reunite, for the after-treatment had been various. He had collected 110 cases of symphyseotomy in this country, with 5 maternal deaths, 16 infantile deaths. Forceps were used in 80.

To avoid symphyseotomy in contracted pelvis one must induce labor near the seventh month, and then the infantile mortality averaged more than fifty per cent., for French statistics on this point did not hold for this country; maternal mortality two to five per cent., or nearly as high as in selected symphyseotomy.

DR. J. CLIFTON EDGAR said he considered himself very fortunate in having witnessed Dr. Ayers operate, for he regarded the method adopted as superior to those of Morisani and Pinard. The mode of extraction was important, for upon it depended to an extent the amount of pubic separation, and this influenced the after-result. To go beyond ten centimetres meant danger of lacerating the vagina and impairing the sacro-iliac joints.

DR. SPENCER BROWN mentioned a case in which he had performed symphyseotomy by Morisani's method twice, finding bony union below, fibrous union above, at the second operation. The hemorrhage back of the joint was larger and more difficult to control at the second operation.

DR. W. T. LUSK gave a detailed description of Pinaud's operation, and showed instruments devised by Farabeuf for measuring the pelvic diameter, diameter of the head, etc. By observing the points laid down there should be no hemorrhage.

DR. DAWBARN read the history of a case of symphyseotomy performed by him January 16, 1894, it being the first time the method practised by Dr. Ayers had ever been employed. He afterward experimented on the cadaver and concluded that it was the best procedure, and recommended it to his friends. His patient had already been in shock, and died a few hours later.

DR. R. A. MURRAY thought the subcutaneous method, using a small knife, was best. The question of version or forceps depended upon the case. According to his observation, cases had done best following version, but where the head was in the pelvis and already moulded forceps should be used.

DR. P. A. HARRIS in one case had kept the parts together by a bandage eight inches wide, laced at the end, but buckles would probably be better. In moderate contraction the mode of delivery could best be determined at the time of labor. For instance, in one case he had performed craniotomy on a dead child, weight ten pounds, while on another occasion he extracted a much smaller child with forceps on the same patient.

DR. H. L. COLLYER would wait before doing symphyseotomy, for much depended upon the size of the

child. In some cases suprapubic symphyseotomy might be best, in others infrapubic. The latter had impressed him favorably. In his case the bones did not separate until the subpubic ligament had been divided, then the separation was sudden and some hemorrhage occurred. A support should be used to prevent too great and sudden separation.

DR. J. F. GRAY, in one case of symphyseotomy, did not divide the subpubic ligament, hoping to get sufficient room for delivery without it, but during extraction the ligament ruptured and some injury to the soft parts was the consequence. There was now perfect union in spite of the fact that the attendants allowed the patient to get up with a very loose bandage during convalescence.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 27, 1895.

HENRY S. STEARNS, M.D., VICE-PRESIDENT, IN THE CHAIR.

Hodgkin's Disease: Occlusion of the Thoracic Duct.

—DR. F. S. MANDLEBAUM presented specimens from a case of Hodgkin's disease in which there was thrombosis of the left innominate, and of the subclavian and internal jugular veins, with occlusion of the thoracic duct, and consequent chylous ascites and chylous hydrothorax. The patient, R. K—, nineteen years of age, had always been well up to July, 1894, at which time a small tumor was noticed on the left side of the neck. It was removed by operation four months later, and then there were some small tumors noticed in the axillary region. She was apparently well up to February, 1895, when a mass appeared at the site of the scar and grew rapidly. The abdomen then became distended. On October 13th she was admitted to the Mount Sinai Hospital. Examination showed large tumors in the neck and axillary region; none in the groin. The right pleural cavity gave clinical evidence of effusion and on aspiration a milk-white fluid was withdrawn. Microscopical and chemical analysis showed it to be a mixture of chyle and serum. The abdomen contained similar fluid. Both cavities were aspirated several times. The total quantity removed from the abdomen was thirty-seven quarts, and about as much oozed from a cannula which was left *in situ*. Twelve quarts were taken from the chest. The urine was clear and gave no evidence of chyluria. There were no filaria found in the blood. The patient finally died of pulmonary edema. The autopsy was made eighteen hours after death. Both pleural cavities and the peritoneal cavity were distended with chylous fluid. There was a large mass of mesenteric and retro-peritoneal glands the size of a child's head. The intestines were apparently normal. There was no involvement of Peyer's patches. The spleen was only slightly enlarged; the liver was congested; the kidneys were apparently normal; the lungs were compressed, and the heart was normal. The mediastinum was filled with glands. The veins of the neck were dissected out, and an organized thrombus found in the innominate of the left side, extending through the subclavian and internal jugular veins to the valves. It was six centimetres in length and firmly adherent. It completely occluded the thoracic duct. The veins were all embedded in and compressed by enormous masses of glands. The thoracic duct was removed, but, with the exception of a few dilated portions, nothing abnormal was found.

DR. THOMAS S. SOUTHWORTH presented a specimen of **Pulmonary Emphysema in an Infant.**—The child was nearly six months old at the time of its death, and it had been bottle-fed on cow's milk prior to coming

into the hospital. On admission, when three and a half months old, it was in a marasmic condition. It was fed on modified milk, and then on peptonized modified milk, but did not thrive. The child died on November 24, 1895. There was no history nor were there any physical signs of involvement of the lung. At the autopsy the heart was found to be normal; the lower lobe of the left lung was bound down by old adhesions; the anterior borders of both lungs were fully distended. The upper lobe posteriorly showed an area of non-aërated tissue, and the lower lobe posteriorly an area of hypostatic congestion. The left lower lobe over which there had been firm adhesions was firm and non-aërated, and contained a cavity about the size of a hazelnut. On the mediastinal surface of the same lung were three or more similar cavities, situated so near the surface of the pleura that it bulged outward. Two of the cavities connected with the main bronchi. There was some pus in the other bronchi but none in these cavities or in the bronchi leading into them. If these cavities were, as they appeared to be, dilatations of the bronchi, the condition was quite rare in such a young infant. No microscopical examination had yet been made of the wall of the cavity.

DR. HENRY POWER said that he would like to ask if it were possible to exclude forcible artificial respiration at birth as the cause of this emphysematous condition.

DR. SOUTHWORTH replied that the appearance of the lung did not seem to him like that of the interstitial emphysema found as a result of forcible artificial respiration. Such an emphysema was usually along the edges of the lung or between the lobes and just beneath the pleura, whereas in this case it appeared to be actually in the substance of the lung.

DR. STEARNS thought that one of the areas exhibited looked very much like an interstitial emphysema.

Syphilitic Osteo-Chondritis.—DR. JAMES EWING presented specimens removed from an infant who had been born in the Sloane Maternity Hospital and had survived only a few days. The mother had active secondary syphilis, and at birth the child had a characteristic maculo-papular eruption, moderate snuffles, and general weakness. A few hours before death there was sudden collapse. At the autopsy, the frontal lobe on the left side was found to have been converted into a small necrotic mass into which there had been a moderate hemorrhage. At the base of the lobe and involving the orbital plate of the frontal bone was a well-marked periostitis with adhesions around the opening into the softened area. There was also an osteitis which had evidently connected with the superior nares on that side. There had apparently been a syphilitic periostitis and osteitis which had established a communication with the brain and given rise to this area of necrosis. On the other side of the anterior fossa there was a similar infiltration of the periosteum, but no affection of the brain. Sections from the side having the more advanced lesions showed only round-cell infiltration, and some fatty degeneration. The wall of the necrotic area was too much decomposed to admit of making sections, and for the same reason no proper histological examination could be made of the viscera. Sections were made of the ends of the long bones at the elbow, knee, and hip; they exhibited the usual syphilitic osteo-chondritis. In the fresh state there appeared to be only a hyperæmic condition. One quite typical feature was a separate centre of ossification beyond the normal zone of ossification. The microscopical appearances were as follows:

The irregularities of the pathological process were seen principally in the ossification zone. The cartilage cells had gone through the usual process of swell-

ing and stratification with absorption of the matrix and final extrusion into the medullary cavity, but in many places the cell spaces were occupied by one or more small round cells as well as by the older cartilage cells. Many cell spaces were occupied by granular matter, partially calcified and apparently derived from the degenerated cartilage matrix. They were often arranged in dense red circles about the cell spaces. The capillary vessels were occasionally the source of minute hemorrhages in the ossifying zone. New blood-vessels were occasionally seen above the ossification zone. The ossification zone itself was very irregular in outline, and sent out linear off-shoots or showed completely isolated areas of calcifying cartilage. The regular process of ossification had been limited in some places by the previous transformation of the cartilage matrix into a tissue composed of small round and fusiform cells, entirely devoid of nuclei. The periosteum was in many places infiltrated with small round cells. In the most advanced focus, *i.e.*, in the superior nares, the medullary spaces surrounding the primary calcifying area were occupied by dense masses of small round cells, fusiform cells, and polynuclear leukocytes. This round-cell infiltration and failure of blood-supply had finally resulted in the ulceration found in the superior nares and anterior cerebral fossa.

DR. STEARNS said that this description appeared to correspond with that of the appearances observed in rachitis, and he would therefore like to know how the ossifying zone in the femur differed from a rachitic zone.

DR. EWING replied that he did not think any sharp distinction could be made.

OUR LONDON LETTER.

(From our Special Correspondent.)

REGISTRATION OF NURSES AND MIDWIVES—UNIVERSITY OF LONDON—RENAL COLIC IN INFANTS—PREVESICAL ABSCESS—SALICYLIC ACID AS A PRESERVATIVE—NOTICE TO AMERICANS IN REGARD TO INTERNATIONAL POSTAGE.

LONDON, January 17, 1896.

THE registration of nurses is a subject which still agitates doctors as well as the nurses themselves. On Tuesday a conference, called by the parliamentary committee of the British Medical Association, was held, with representatives of those nursing institutions which chose to send them. The move can hardly be called successful, for such important bodies as the Nightingale Fund, the London Hospital, Charing Cross and Middlesex Hospitals, the Leeds, the Marylebone, and the Westminster Training-Schools, repudiated it, and replied to the invitation that legal registration was "inexpedient in principle, injurious to the best interests of nurses, and of doubtful public benefit." Nevertheless, the advocates of compulsory registration made a bold stand for their plan. Of course, the question of midwives or midwifery nurses was sure to come up at such a meeting and distract attention. Many discordant suggestions were offered, but nothing practical was the outcome of the conference. The representatives of institutions were asked to vote, with a result that five held up their hands for legislation and six against. Dr. B. Fenwick declared that a bill was being drafted and would shortly be published, and was reproved for taking part in such action until the committee to which his resolution had been referred had had the opportunity of consulting the institutions. A further show of hands demonstrated that the representa-

tives of institutions present disapproved of medical supervision over midwifery nurses. Many attempts to define a midwifery nurse have been made, but all definitions seem to be objected to, and the discussions about nurses threaten to be interminable. Another definition is demanded by one party, viz., that of "natural labor," as it is proposed to restrict midwives to such cases. How? ask the opponents of the scheme, and the advocates make no satisfactory reply.

Another question which your readers may think is interminable, is the reconstruction of the University of London. A meeting of convocation will be held next week, and it is anticipated that an acrimonious debate will ensue. The two parties are issuing a strong whip, and as the government has intimated that the opinion of convocation should be consulted, we may expect that the meeting will be a full one and the debate animated.

Some interesting cases of renal colic in infants were brought forward at the Medico-Chirurgical Society meeting on Tuesday. They all occurred in infants with gouty parentage, all had symptoms of renal colic supervening suddenly, and there was nothing prior to these attacks to lead to medical advice being taken. No calculi were found, but much uric acid was passed and small mortar-like masses which were found to consist largely of uric acid. All were children of the well-to-do classes. One speaker said he was familiar with similar cases among children of the poor, and attributed them rather to the rheumatic diathesis. It was suggested that salt might be given, as it increased the solubility of uric acid.

Another paper at this meeting was on "Prevesical Abscess," founded on four cases which had all given rise to difficulty of diagnosis. These cases are rare here, but Brigade-Surgeon Macleod said he had seen many of them in India. The natives, when pulled down by malaria, were prone to suppurate in loose connective tissues, and the prevesical space offered a convenient situation. He had known such an abscess to reach up to the umbilicus. Diagnosis was to be made, he said, by aspiration, and treatment by incision, but recovery was rather slow.

A prosecution under the adulteration of food and drugs acts for selling wines into which a little salicylic acid had been added as a preservative, has led to no result, except an exhibition of the differences of the experts called in. It seems almost a pity that this prosecution should have been commenced, as the amount used was very small, the object reasonable, and any injurious effect on the health hardly credible. And yet this decision may encourage others, who will appeal to it as a precedent, to resort to more decided adulteration.

American correspondents, attention! When you write to England, take care to put the proper stamps on your letters. Two or three friends of mine are making disagreeable remarks about your inattention to this matter, and, really, I hardly know how to defend you. It is not advertisers and traders who are the culprits. The children of this world are wiser in their generation, and know that a fine of 3*d* on a circular is not likely to predispose the receiver in favor of the goods offered. No, it is men of light and leading, who are too much in the clouds to remember that international postage is not the same as national. I have promised to draw your readers' attention to this insignificant grievance, and hereby fulfil my promise. No doubt a word in the MEDICAL RECORD will suffice, so far as medical correspondents are concerned.

An Active Germ.—Cohn says a single germ could, under good conditions, multiply in three days to 4,772 billions, and make a mass weighing 7,500 tons.

OUR PARIS LETTER.

(From our Special Correspondent.)

FRENCH WINTER RESORTS—NICE—MENTONE—MONTE CARLO—HYÈRES—ALGIERS—SAINT RAPHAEL—COMPARATIVE MERITS OF DRAINAGE—PREVAILING ATMOSPHERIC CONDITIONS PREFERABLE TO FLORIDA.

PARIS, January 10, 1896.

THE new year has begun with overcast sky and cold, damp weather, which has driven many, especially invalids, to warmer climes. The School of Medicine opened its doors again on the 6th instant, after the short vacation, for the remainder of the winter semester and professional matters generally are getting into swing once more, although the season is acknowledged by all, physicians and chemists, to be a rather dull one.

The Riviera seems to be in vogue with doctor and patient alike, and it is Nice that is usually recommended, more especially in cases of chronic disease of the respiratory organs, laryngeal troubles, certain affections of the spinal cord, and neurasthenia, although as a general rule neurotic patients do not do well at the seaside. The air is dry and bracing, with cold winds at times and sometimes snow. The climate of Cannes much resembles that of Nice and the same class of patients is sent there. At Mentone the changes of temperature are less sudden than at either Nice or Cannes, and the climate is altogether more equable. There are several gaps or wide ravines down which the wind sweeps sometimes, making it very objectionable and even dangerous in some cases for delicate people; but this is in Mentone itself, which should not be recommended so strongly as the east end or East Bay, as it is called; this part of the town is entirely hemmed in at the back by a semicircular range of mountains, quite like an amphitheatre, affording protection from the mistral.

Dr. Henry Bennet, in his valuable work entitled "Winter and Spring on the Shores and Islands of the Mediterranean," assures us after many years of personal observation and study that the moisture-laden sea breeze which is drawn in daily by the sun's heat in cloudless weather is arrested by this amphitheatre of mountains, which it cannot pass. The colder atmosphere of the elevated regions condenses its moisture and so forms a haze over the landscape from about 11 A.M. These condensed vapors soften the atmosphere in an exceptional manner, and no doubt this explains the fact that so many invalids improve, or even get well at Mentone, while other regions of the North Mediterranean coast and the Riviera disagree with them.

Monte Carlo, situated between Nice and Mentone, although supposed to be an independent principality, is really under the protection of France and, being actually on the French Riviera, may very properly be mentioned as a French winter resort. It is somewhat higher than Mentone and has likewise a background of mountains. Patients with locomotor ataxia sometimes do well in its climate.

But the climate which an unusually large number of invalids are seeking this month is that of Algiers, on the south coast of the Mediterranean, for that, too, is a French winter resort, although situated in Africa. Algiers possesses among other advantages this very important one—phthisical patients are not crowded together as they often are in the hotels of the East Bay of Mentone. We all know what a depressing influence is exerted upon patients as a mass when many frequent a small resort. It does not, however, come within the province of an ordinary letter to do more than mention this *en passant*.

Algiers is especially recommended for diseases of the throat and chest; some rheumatic and gouty pa-

tients also do well there, but abundant observation has shown that such cases usually derive more benefit away from the sea. There is about the same degree of humidity as in the East Bay of Mentone and the temperature is higher than at any other Mediterranean station, the mean during the winter months being 61° F. Residence should always be taken on the Mustapha Superior, which is much higher than Algiers itself and close by the city. Patients of the class referred to always do better in that section and there is less humidity there than in the town proper. The Atlas Mountains, owing to their proximity, form a barrier to the sirocco and contribute to make the climate of Algiers the most equable of any of the French winter resorts. As regards malaria, it is to be feared only in low marshy localities, where there is stagnant fresh water and vegetable decomposition. The rainfall averages about the same on both Mediterranean shores.

As there is a certain class of cases which it is unadvisable to send to the mountains, so there is another class that cannot be sent to the seaside. The combination of sea and mountain climate, the blended geographical and meteorological conditions that are to be found almost anywhere on the Riviera or in and about Algiers, explain why such cases sometimes do well in either of the places mentioned. Instead of sending their wealthy patients to Aiken, Thomasville, Asheville, Gainesville, or the Indian River, our American confrères would do infinitely better to advise a winter *outré mer*, in one of the resorts of which we are now speaking, and above all in one of the smaller stations near Algiers, rather than in the city itself.

A new sanitarium has just been created at Birmandreil in the environs of Algiers by Dr. Verhaeren, which is very highly spoken of from a professional point of view as well as in other respects. It is designed chiefly for the reception of tuberculous cases. The ground is calcareous and free from humidity, provided with good spring water, and at considerable elevation above the level of the sea.¹ There is an extended view of the surrounding country and sea, while the quiet that prevails has a very happy moral effect, acting at the same time as a calnative of the nervous system. A few miles farther inland the atmosphere is still purer and perhaps the driest in the world. There is also to be found good hunting, a sport so valuable in the treatment of phthisical subjects.

Returning now from the southern coast of the Mediterranean to the northern, two French winter stations which, although possessing less *renommée* than those already spoken of, should not be passed over in silence. These are Hyères and Saint Raphael, the former by far the better of the two. Hyères itself is situated on the southern slope of the Maurettes hills, attaining here a height of about seven hundred feet. The mean temperature during the winter months is 55° F., with a mean humidity of the air during the entire year of fifty-eight per cent. The hour of sunset is the dangerous one here, as it is at any of the Riviera resorts. Patients should be cautioned to remain indoors at that time, and thus avoid the sudden chill and atmospheric change to which they would otherwise be exposed. Three fine avenues, planted with palm trees, have obtained for Hyères quite a reputation and the name "Hyères les Palmiers." The climate on the whole is rather a dry and stimulating one.

Saint Raphael is a very pretty place, but unfortunately has no protecting hills nor mountain range behind it, and is thus left open to the full force of the mistral. We should, therefore, hesitate to send there

patients at all seriously affected. As regards drainage there is a natural drainage by declivity, but although great improvements have been made in this line considerable yet remains to be done, as cases of typhoid fever on the Riviera still attest. The same system of drainage is in practice in all the places noted, any one of which, with the exception of Algiers, may be reached in from twenty to twenty-three hours from Paris.

Invalids usually leave Paris in the cold and wet and are rapidly transported to Marseilles. From there the railway runs along the seashore parallel with the celebrated Corniche road, passing in succession through the different health stations until Mentone, the last one and touching the Italian frontier, is reached, with bright sunshine overhead and the clear blue water of the Mediterranean, with its white foamy waves breaking against the red-brown cliffs on the one side and the olive-covered slopes of the Alps Maritimes on the other. With orange, lemon, and palm trees almost everywhere, among picturesque villas and casinos with their gardens of roses and japonicas in full bloom, the invalid, already brightened, arrives at the station chosen and, at the end of the winter, is encouraged to return home, if not cured at least greatly benefited.

OUR PHILADELPHIA LETTER.

(From our Special Correspondent.)

PUBLIC BATHS IN PHILADELPHIA—LEIDY FELLOWSHIP—
PHILADELPHIA COUNTY SOCIETY—PUERPERAL FEVER
—HOSPITAL FOR CONVALESCENT CHILDREN—AC-
CIDENT TO H. C. WOOD.

THE success of the People's Baths and the Riverside Baths in New York City, for the organization of which much credit is due Dr. Simon Baruch, has stimulated other cities to similar undertakings. The Public Baths Association of Philadelphia is a year old, and has collected \$24,850, to form part of a fund of \$50,000 or \$60,000, which is to be devoted to the building and equipment of a suitable bathing establishment for popular use. It is intended to erect one or more bath-houses and laundries, where for a small fee persons of both sexes can obtain hot or cold baths at all seasons, and where women can do their family washing. A lot has already been purchased for the purpose. There will be no swimming-pool, showerbaths only being provided. The building will contain fifty-seven baths, and a small number of tubs for women and children. Each bather will have a separate and private apartment in which to dress and bathe, and will be supplied with soap and towels. It is estimated that provision will exist for one thousand baths a day.

As already noted in the MEDICAL RECORD, it has been proposed to establish, with a fund of \$30,000, a Fellowship in Anatomy in the University of Pennsylvania, as a memorial of the late distinguished Joseph Leidy, who for thirty-eight years occupied with conspicuous ability the chair of anatomy in the University Medical School, and who died five years ago, at the age of sixty-eight years. Of this sum \$7,000 has already been subscribed.

At the business meeting of the Philadelphia County Medical Society, on January 15th, Dr. James C. Wilson was re-elected President, and Dr. James Tyson First Vice-President. Dr. T. J. Mays was elected Second Vice-President, and Dr. F. P. Henry Censor. Delegates to the American Medical Association and to the Medical Society of the State of Pennsylvania were also elected. The report of the directors showed the finances of the society to be in a tangled condition.

¹ The elevation of places about Algiers averages from 600 to 1,800 feet above sea level.

appropriations of a given year having been used to pay the obligations of the preceding year.

On the evening of January 16th, Dr. William T. Lusk, of New York City, read a paper before the Section of Gynecology of the College of Physicians, on "Recent Bacteriological Investigations Concerning the Nature of Puerperal Fever." The discussion that followed disclosed how widely at variance are the views of gynecologists as to the use of ante-partum and post-partum douches and of the uterine curette. While Dr. Lusk expressed the hope that good might come from the performance of hysterectomy in certain cases of puerperal infection, many doubts were expressed as to the ability to recognize and select the cases at an early enough period to secure the good of which the operation might be capable. At the conclusion of the meeting a well-attended reception was tendered Dr. Lusk at the house of the retiring President, Dr. C. B. Penrose. Dr. B. C. Hirst was elected President of the section for the ensuing year.

A bequest of \$20,000 has been made by Mrs. Anna R. Aspinwall, of Pittsburg, who died in Edinburgh a short time ago, for the purpose of founding a hospital for convalescent children in Philadelphia, in which female children are to be given the preference.

Dr. William M. L. Rickards, who had been engaged in the practice of medicine for more than fifty years, died on January 17th, at the age of seventy-four, in consequence of gastric ulceration. He graduated from the University of Pennsylvania in 1843.

Dr. H. C. Wood, professor of materia medica and therapeutics in the University of Pennsylvania, fell from his bicycle on January 16th, in endeavoring to avoid a trolley-car, and collided with a carriage, being kicked by the horse and run over by the vehicle. Fortunately the injuries were not serious, and Dr. Wood will soon be at his work again.

"ANTIPHTHISIN."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a letter to the MEDICAL RECORD of January 18th, Dr. Joseph Muir criticises an inference expressed in a recently published article by Dr. Baldwin and myself on "antiphthisin."

Dr. Muir's letter conveys the impression that we were ignorant of the fact that the tubercle bacillus can be grown on media presenting a slightly acid reaction, and that the inference above referred to, which we drew from our observations, is thereby rendered erroneous.

As I have been engaged in growing cultures of the tubercle bacillus almost uninterruptedly for ten years, had on hand many flasks of these cultures on Lubinski's¹ unneutralized potato broth, which gave a very perceptible acid reaction, before the "antiphthisin" article was written, and had shown before the New York Academy of Medicine, as long as five or six years ago, cultures on unneutralized potato grown according to the method described by Pawlowski,² when these were not so familiar to bacteriologists as at present, I was cognizant of the tolerance to slight acidity of the medium which is displayed within restricted limits by the tubercle bacillus.

De Schweinitz's³ experience as to the production of acidity in the medium coincides with ours: "The reaction of the media when inoculated is slightly alkaline. As the growth increases it becomes less so, and finally it is acid in reaction."

De Schweinitz's asparagin medium, the various me-

dia described by Proskauer and Beck,⁴ as well as Lubinski's potato broth, owe their acidity to the presence of acid salts, usually phosphates, but there is a limit to the tolerance of the bacillus for this acidity.

There is no reason, however, why this limited tolerance should invalidate in any way the observations in question, or the very moderately expressed deduction which we drew from them, and which refers to the acidity induced in the medium by growth of the germs, the observed facts being briefly as follows:

That the usual shallow layer of a slightly alkaline or neutral medium becomes markedly acid by the fact of having had a culture of tubercle bacilli grown on its surface until such a culture has completed its development, and that "the addition without heat of a little alkali to a filtered culture medium, upon which bacilli have ceased to grow, renders it again fit for the development of a second crop of germs, so long as any nutriment remains."

Since the acid was not present at the time of planting, since it is therefore induced in the medium by the growth of the germs, and since its neutralization enables a second crop to develop freely on the surface of the medium, we feel warranted in our moderately expressed inference: "It may be inferred that the limitation of the growth of the tubercle bacillus in such a culture medium is most likely due to the acidity induced in the medium, rather than to any specific germicidal substance produced therein."

An analogous effect is noted by Hueppe,⁴ in regard to the inhibiting influence produced on the bacteria of milk fermentation by the acid which they generate in the medium, and the continuance of the growth after its neutralization.

"When these acids are formed by the bacteria, the further development stops within a certain limit, determined by me for lactic acid—similar to that which obtains in yeast fermentation by the effect of alcohol.

"If one neutralizes the acid, e.g., by addition of calcium carbonate, the decomposition again proceeds further" (Hueppe).²

ADVERTISING IN THE COUNTY REGISTER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The writer has received a notice to send \$3.00 to the treasurer of the Medical Society of the County of New York, the annual dues in advance up to October 26, 1896. It may be presumed that this assessment is to cover the outlay for publishing the "Medical Directory of the City of New York" for 1895. If this be so, I would like to inquire by what authority the editor of the "Directory" publishes the numerous advertisements of trade-marked medical goods, etc., along with the list of names in the "Directory"? This advertising I cannot endorse, and there are other members of the society of the same way of thinking. I am quite willing to be assessed to aid in printing the list of names, but do not wish to contribute toward advertising the class of goods referred to above, unless it can be shown that the society approves of such outlay, in which case there seems no other course left but to resign from the society.

The Value of the Comparative Method in the Study of Pathology.—The following abstract of Dr. Roswell Park's presidential address before the Medical Society of the State of New York, at its recent meeting in Albany, was received too late to be inserted in the body of the report of said meeting: His plea was for a further extension of methods of comparative study in the investigation of disease and departure from the normal standard. While a man might be perfectly competent to reduce a fractured fibula who had never heard that the fibula was a disappearing relic, and that in many of the lower animals it was the larger bone, there nevertheless was no reason why in the interests of higher medical education this fact should not be perfectly familiar to him and to all. While admitting that such knowledge (several illustrations having been given) was desirable, the question arose, how should it be taught? for at present it was known to but few.

First of all, we must not lose sight of the fact that our bodies are aggregations of cells, each of which has its own individuality. Every organized being is a republic of cells, but it was not widely enough appreciated that, as in a republic of citizens a little disturbance in one region may bring about by most unexpected agencies a disturbance or even a revolution, so in the bodies alike of plants and animals cellular disturbance at one point was sure to affect to greater or less extent the entire economy. In higher animal and vegetable forms, however, the cellular organization was altogether too complex to permit a study of the conditions which so disturbed interrelation of parts. We must begin by study of organisms vastly simpler—begin the study of the activity of cells in the lowest and most immature organisms first. It was by studying inflammation in the lower organisms that Metschnikoff had added so greatly to our knowledge of this process. At this point the speaker dwelt on some of the knowledge of cellular pathology which had been gained by comparative study. The formation of tumors in trees was interesting. Among the influences were cold and parasites. For the cellular pathologist a tumor in an animal or upon a tree was practically the same. Malignancy of tumor formation was largely a process of cell degeneration and incompetence. In cancer atavism could be traced back to the hydroid stage, where simple fission was the prevailing method of multiplication, in consequence of which we had a longer lived and more aggressive cell growth which we called malignant. Neoplasms were less common in lower animals.

Among the most remarkable phenomena pertaining to cells was the tendency to reappearance of traits peculiar to remote ancestors, and quite out of keeping with cells in their present locations. Here the speaker referred to a number of congenital malformations.

Reversion to earlier types in avian and reptilian stages was shown in our liver cells, where the tendency was often to the elimination of nitrogenous materials

in the form of uric acid rather than urea. Garrod said: "Our gouty patients are a sort of birds." Goitre was of a reversionary type. A conspicuous example of atavism was seen in the mutual convertibility of skin and mucous membrane.

His plea, in closing, was that men in various branches of scientific work should come together and make common stock of their knowledge. There existed to-day no works in any language on comparative pathology. The ideal work would require two, three, or more volumes, in condensed form, to be placed in the hands of every second-year student. He feared that not until this was done could medicine claim to be really liberal.

The president was tendered a vote of thanks for his able address.

Beri-Beri.—Max Glogner, of Samarang, says that most of the cases of beri-beri on which he made his observations had been a considerable time under observation, and suffered from a slight intermittent fever. Scheube and Baelz had noted such a fever as occurring in forty-five or fifty per cent. of all cases of beri-beri. Glogner has already recorded that in most of his cases he found living amœba-like organisms present in the red corpuscles. Although these organisms greatly resembled the plasmodia found by Laveran and others in cases of malaria, Glogner, after taking into consideration the clinical differences between malaria and beri-beri, came to the conclusion that the micro-organisms in the two diseases were probably different, in spite of their similarity in appearance. However, in a further series of cases, in which multiple neuritis had commenced with fever, Glogner found not only the amœboid organisms, but also the pigmented, sickle-shaped, and oval forms described by Laveran. In other cases of multiple neuritis, which likewise began with fever, he could find none of these microbes; he has, therefore, come to the conclusion that these microbes must not be regarded as the cause of beri-beri, but rather as a sign that the patients really had malaria, of which the multiple neuritis was a sequela; in fact, that the multiple neuritis followed malaria, just as in Europe it has been observed to follow diphtheria, enteric fever, influenza, etc. Leyden long ago suggested that the circulation of ptomaines in the blood was the cause of multiple neuritis following infectious diseases; Glogner thinks that such a ptomaine occurring in cases of malaria may cause a multiple neuritis, which in the tropics may be set down as beri-beri. In this supposition he is confirmed by statistics of the geographical distribution of the two diseases. He believes that what has been called "beri-beri" is not always etiologically the same disease.—*British Medical Journal*.

Death as Read in the Face.—A rather curious discovery has been made with reference to soldiers killed in battle. On the authority of several English army surgeons, it can be stated that the cause of death is clearly shown in the expression of the face of a corpse on the field of battle. Those who have been killed by sword thrusts have a look of repose; if it was a bullet that killed, pain, often of the most frightful nature, is clearly depicted.—*Medical Review*.

A Prospective Fee.—The Nawab Fakr-ul-Mulk must have great confidence in the integrity of his medical attendant, for he has let it out that the latter is to receive an immense fortune upon his patient's death. The *Deccan Budget* says that it is not often that anybody meets with a windfall such as Dr. Dyce, the medical attendant to Nawab Fakr-ul-Mulk, has come in for, or rather expects to come in for. We have had the pleasure to witness a genuine document by which Dr. Dyce is entitled to inherit £600,000 in England and Rs. 2,000,000 in India.

SUBPHRENIC ABSCESS.

BY CARL BECK, M.D.,

PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE; ATTENDING SURGEON, ST. MARK'S HOSPITAL, GERMAN POLIKLINIK, WEST SIDE GERMAN DISPENSARY, ETC.

BUT few years have elapsed since subphrenic abscess was granted a place in medical literature. It is therefore not surprising that even the most modern and complete text-books lack a description of this important condition.

So far as my knowledge goes, R. F. Weir¹ and S. J. Meltzer,² both of New York, are the only ones in this country who have published cases.

Notwithstanding surgery owes most of its recent development to advances of the natural sciences, especially bacteriology, yet here surgery has been the donor by disclosing to pathology as well as to internal medicine the mysteries of this disease.

It was reserved to the genius of a Richard von Volkmann³ to show, as early as 1879, that abscesses situated below the diaphragm can be reached and cured by the knife. His bold yet successful procedure of opening the pleural cavity and incising the diaphragm called the interest of the whole medical world to this new subject.

In the following year Leyden⁴ published his views upon this condition from the standpoint of general medicine, and to him is due the credit of having offered the first clear and simple methods for its diagnosis. How much the knowledge of this subject has increased is evident from the fact that, while from 1879 to 1890 only twenty-eight operations were performed for subphrenic abscesses, the period from 1890 to 1893 shows thirty-two cases. The record has since risen to one hundred and seventy-nine cases, seventy-five of which were operated upon.⁵ Notwithstanding the long array of cases, there are many points concerning the origin of subphrenic abscess that still remain obscure. This is the more to be deplored in that here, as in many other suppurative processes, early diagnosis is essential to successful surgical treatment. Even the most thorough observers sometimes meet with great difficulties in diagnosis, difficulties which can be overcome only by clearing up the manifold etiological factors.

A remarkable effort in this direction was recently made by K. Maydl,⁶ who classified subphrenic abscesses into twelve groups, according to their anatomical point of origin. At the same time the primary disease causing the abscess was considered, whenever possible. Since diagnosis and prognosis, as well as therapy, are naturally dependent upon the seat of the primary affection, I have adopted the anatomical principle as the basis for my own deductions. It is fitting, therefore, before going further, to consider the

topography and pathological anatomy of the disease as the foundation for diagnosis, prognosis, and therapy.

Topography.—The subphrenic space, in which subphrenic abscess forms, is bounded by the epigastrium and the two hypochondria. The right hypochondrium contains the right lobe of the liver, the sharp lower margin of which is overlapped by the gall bladder in the region of the cartilages of the ninth and tenth ribs. Below the liver is the right half of the transverse colon. The right suprarenal capsule and the upper margin of the right kidney, which always leaves a slight impression upon the liver, occupy the most dependent part of the right hypochondrium.

In the left hypochondrium is the fundus ventriculi, covered by the larger portion of the left lobe of the liver. A little further below lies the spleen, connected with the curvature of the stomach by the ligamentum

FIG. 1.—Vertical Section through the Human Body, one inch to the right of the External Margin of the Right Rectus Abdominis.

gastro-lienale and the vasa brevia. In front of the spleen lies the left part of the transverse colon. That part of the epigastrium adjacent to the anterior abdominal wall contains a part of the left lobe of the liver, separated from the wall of the abdomen by the suspensory ligament. The pylorus and a portion of the duodenum are below the liver.

About on a level with the lower margin of the nipple (lower margin of ninth to eleventh dorsal vertebra posteriorly), the diaphragm forms a figure-of-eight, whose knot is situated between the œsophagus and the pericardium. The peritoneal coat of these organs is incomplete at three portions: 1, At the suspensory ligament of the liver; 2, at the place where the lobus Spigelii touches the minor omental bursa, at the lower

⁶ "Ueber subphrenische Abscesse," Wien, 1894.

surface of the liver; and 3, at the portion situated between the end of the bursa omenti and the posterior end of the peritoneal cavity, which adapts itself to the liver from in front.

Fig. 1 shows the upper half of the anterior surface of the left kidney covered by peritoneum, while the lower half is not covered by serosa, and behind the stomach is separated from the great omental bursa by the suprarenal capsule and the pancreas. The anterior surface of the stomach has a serous coat which faces the great peritoneal cavity, while its posterior serous coat forms the anterior wall of the great omental bursa. The posterior portion of the same covers the anterior surface of the pancreas and the end of the duodenum. The serous coat of the stomach running downward covers the transverse colon. The upper portion of the transverse mesocolon passes over to the pancreas, thereby forming the posterior wall of the great omental bursa, while the lower portion passes over into the mesentery of the small intestine.

These anatomical facts show that, with the exception of the cardiac region and the junction of the great and small omental bursa, the stomach does not anywhere

FIG. 2.—Vertical Section through the Right Rectus Abdominis.

adapt itself directly to the subphrenium, but touches it with a serous coat which comes from another organ. Consequently the stomach may be the medium of intraperitoneal as well as of extraperitoneal subphrenic abscess.

Extraperitoneal abscess could also originate from the left lobe of the liver, if it perforate alongside the triangular ligament into the subphrenic space.

On the right side (see Fig. 2), the whole diaphragmatic cavity is filled by the right lobe of the liver. Posteriorly the right kidney slightly indents the liver, touching the diaphragm with the upper half of its posterior surface and the psoas muscle with the lower half. The liver is covered with peritoneum from its lower margin up to the hilus. The posterior surface of its convexity, as well as its posterior margin and the posterior half of its lower surface, are not covered

with peritoneum toward the median line, but have a peritoneal coat laterally. Only the upper surface adapts itself to the diaphragm directly.

In front of the lower surface of the kidney is the duodenum, partly covered by the serosa of the small omental bursa. In front of it is the pyloric portion of the stomach, whose anterior surface is coated with the serosa of the lower anterior surface of the liver. The transverse colon is often found in front of the pylorus, while neither the transverse nor the ascending colon has ever been found between the convexity of the liver and the anterior abdominal wall, as the external convexity of the liver always lies close to the abdominal wall.

The peritoneal coat of the liver sometimes embraces the gall bladder completely, forming a mesentery for it, from which it hangs; sometimes it merely passes over its under surface and binds it closely to the under surface of the liver. The pancreas is separated from the posterior surface of the stomach by the great and small omental bursæ, and lies very close to the diaphragm.

Pathological Anatomy.—Subphrenic abscesses (synonyms: hypophrenic abscess, subdiaphragmatic abscess, subphrenic empyema, empyema hypophrenicum, pyopneumothorax subphrenicus, perigastric abscess, perigastritis, false pneumothorax, localized tympanites, suppurative perihepatitis, suprahepatic abscess, pneumoperforative peritonitis, subperitonitis) are divided into intraperitoneal and extraperitoneal.

In the first variety the abscess lies wholly within the peritoneal cavity. In the second variety the abscess wall may or may not be formed in part by peritoneum, but in any case only by its external surface. An important differential point in these conditions is, that, since an extraperitoneal abscess never lifts the peritoneal serosa of the diaphragm, it is perforce confined within narrow limits and consequently does not fill the subphrenium so completely as does one of the intraperitoneal variety. Another characteristic feature of the extraperitoneal form is that it has a greater tendency to perforate into the thorax, especially into the pleural sac.

Intraperitoneal subphrenic abscess assumes an entirely different significance according as it is located on the right or the left side of the falciform ligament. This ligament forms the median line between the right and left subphrenium. As the whole right subphrenic space is filled by the liver, the lower wall of an abscess situated on the right side is formed by the upper convexity of the liver, while on the left side the stomach, as well as the spleen, the transverse colon, and the left lobe of the liver, may form a wall.

Extraperitoneal abscesses are most frequently found on the right side. This is quite natural, since clinical as well as post-mortem observation has very often traced their source to the caecal region. Rarely this form of abscess arises from the kidneys or ribs.

Diagnosis.—Regarding differential diagnosis, three questions most frequently arise, namely: Is the condition to be considered a pyothorax, a subphrenic abscess, or a subphrenic pyopneumothorax? The diagnostic points of these three conditions, as first advanced by Leyden, almost unexceptionally remain authoritative. In subphrenic pyopneumothorax deep percussion above the retracted lung yields resonance. From the third rib downward it is generally full and tympanitic. Instead of liver dulness on the right thoracic margin, a profound and full sound is present. Below the right costal arch the liver is pushed far into the abdomen, and its lower border is easily recognized by palpation and percussion.

Auscultation shows the absence of respiratory murmur from the third rib downward. Amphoric breathing and metallic tinkling take its place. In auscultatory percussion, metallic phenomena are noticed. There is no vocal fremitus on the lower part of the

right thorax. The succussion sound can be heard by shaking the patient. If the effusion can be made out by percussion on the lower thoracic portion, it is found to change its seat easily and quickly, whenever the patient is turned. If the effusion is situated on the right side, the heart will be slightly displaced toward the left, and *vice versa*.

It must be remembered, furthermore, that an admixture of gas is a characteristic feature of subphrenic pneumothorax. This gas is the product of putrid decomposition, and seems to give the pus a capacity for rapidly eroding the surrounding tissue. An exploratory puncture reveals ichorous pus of offensive odor. It is superfluous to say that when the admixture of gas is recognized by an exploratory puncture, a most valuable point for differential diagnosis is obtained.

The history is often an important guide as to the location of the abscess. In subphrenic abscess there is often a history of previous abdominal disturbance. On the contrary, there is no history of cough and expectoration. The heart is little, if at all, displaced, and there is no ectasy of the thorax or of the intercostal spaces. In the lungs, vesicular breathing is found below the clavicle. Pectoral fremitus is also clearly perceptible. There is a well-marked limit to the region of vesicular breathing, below which the expiratory murmur is replaced by amphoric sounds. Deep inspiration pushes the boundary line of the region of vesicular breathing much farther down, into areas in which formerly no respiratory murmur could be perceived. This would indicate a well-marked separation between the lungs and the abscess cavity, the boundary line of the lungs protruding toward the abscess cavity during deep inspiration.

It is sometimes impossible to distinguish an encysted pleuritic effusion from a subphrenic abscess. The pathognomonic signs of pleuritic effusion urged by Leyden were, absence of cough and expectoration, slight displacement of heart, and rapid change of note if the patient is rapidly turned. But, according to my own observation,¹ pyothorax sometimes occurs without these symptoms.

In reference to the absence of thoracic ectasy and the inversion of the intercostal spaces as pathognomonic of subphrenic pyopneumo-thorax, it must be stated that Herrlich holds precisely the opposite view, and

FIG. 3.—Left-Sided Pyopneumo thorax.

claims that ectasy of the lower thoracic sphere is a decided characteristic of the presence of this condition.

The motions of the exploratory needle, introduced into the abscess, were also regarded as pathognomonic by Fuerbringer. But, bearing in mind that in subphrenic abscess the function of the diaphragm is greatly impaired, and that, furthermore, the point of the exploratory needle may be fixed by the diaphragm as well as by the abscess membrane, neither the pres-

ence nor the absence of the motions can be regarded as determining pathognomonic factors.

If the diaphragm, being pushed up high, tightly adheres to the thoracic walls, the needle may invade the subphrenic abscess without being fixed by the diaphragm. Consequently, even if the diaphragm should still be able to make respiratory movements, the needle would not necessarily be moved by them.

All these points go to show that, aside from the history, there are but few absolutely reliable pathognomonic data for the diagnosis of subphrenic abscess. Practically, however, it will make little difference to

FIG. 4.—Left-Sided Subphrenic Abscess (containing gas).

the surgeon whether pyothorax or subphrenic abscess is present, as the essential part of the treatment of either condition is free opening. The main question will always remain as to the presence of an abscess. Whenever suspicion arises, the introduction of the exploratory needle should be a matter of course. The same aseptic precautions should be observed as in any other operation. The skin of the patient, as well as the hands of the surgeon, should be rendered clean, and the syringe and needle thoroughly sterile. If the first trial be negative, the needle should be introduced several times into different portions, as the pus cavity may either be of small extent, or may contain a cheesy accumulation, or, finally, may be divided into several minor cavities by adhesions.

In the first event the cavity might be missed altogether by the exploratory needle, and in the second the needle, being introduced into the solid cheesy mass, could draw no pus. After each negative result, therefore, a wire should be pushed through the needle (which should not be of too small a calibre): this procedure sometimes brings a little pus into the needle. Occasionally it will be useful to fill the syringe with sterile water after the operation, and force the water through the needle into a Petri dish containing gelatin. In case cheesy masses are present, small particles are sometimes drawn into the calibre of the needle which cannot be perceived by the unaided eye; but which, by being mixed with the sterile water, can be recognized under the microscope.

Prognosis.—Experience leads me to conclude that the prognosis of the subphrenic abscess of malignant origin, such as carcinoma pylori for instance, depends almost entirely upon early diagnosis. I hope not to be reproached because the percentage of mortality in my cases is *nil*, but I may state at once that it has so far been my good fortune to encounter cases of a more favorable etiology than those generally found. I am confident that I shall meet with a higher mortality rate as soon as I have opportunity to see more cases. Still I may say that the mortality rate of fifty per cent., as given by Maydl, is much too high. Considering that Scheurle's mortality rate was 82.5 per cent., while Sachs in a series of six cases lost none, it can clearly

¹ "Pyothorax and its Treatment," MEDICAL RECORD, May 19, 1894.

be seen that the kinds of cases reported differ remarkably. Furthermore, it must be considered that very few of the cases reported in the unfortunate series were operated upon. An approximate judgment can be based only on a large number of well-defined cases.

Spontaneous healing of the subphrenic abscess is extremely rare, as is that of pyothorax. Perforation may take place into a hollow organ, like the stomach, or a bronchus, or the bladder. Literature shows spontaneous healing of subphrenic abscess six times in one hundred and four cases. As the mechanism of such natural healing is unknown to us, and therefore cannot be controlled by any medical therapy, it can only be by chance that a cure is thus effected.

Since the pathology of appendicitis has been more widely recognized, poulticing and opium have ceased to be the panaceas. The expectant treatment of subphrenic abscess also will be discarded as soon as the condition has become more closely studied. I have already said that the important point in prognosis is the source of the abscess.

Microscopical and bacteriological examination of the aspirated pus yielded no prognostic aid in my own cases. But it may fairly be assumed that with greater interest in this disease and the higher development of our examining methods, more valuable information on these points will be obtained. It is to be regretted that, according to the reports of reliable investigators, pus-culture experiments are negative. Probably the microbes are dead, since even the pus taken from the subphrenic abscess of tuberculous patients has repeatedly failed to produce reaction when injected into rabbits.

So far there have been found in the pus of these abscesses the staphylococcus pyogenes aureus, streptococcus, bacillus coli communis, bacillus pyogenes fœtidus (Passet), micrococcus tetragonus, various species of proteus (Hauser), saccharomyces, and diplococcus citreus conglomeratus. As the analogy with pyothorax is obvious, it may be remembered that the pus of that condition shows streptococcus, bacillus tuberculosis, typhus bacillus, staphylococcus aureus and albus, and diplococcus lanceolatus (Fraenkel). In 109 cases of pyothorax Netter found streptococcus 50 times, pneumococcus 32 times, saprogenous micro-organisms 15 times, Koch's bacillus 12 times. The presence of pneumococcus or staphylococcus in subphrenic abscess would suggest a pulmonary origin. We know that the presence of streptococcus in pyothorax seems to favor the formation of solid masses in the effusion, and, furthermore, that this coccus has a predilection for the infectious diseases of adults, whereas Fraenkel's coccus shows the most benign character of all microbes found in pyothorax. Whether this is accidental or not, and how much the analogy can be utilized for the prognosis of subphrenic abscess, the future must show.

Undoubtedly the prognosis is also influenced by the extent of the accumulation, the consistency, appearance, and odor of the pus, the age and the constitution of the patient, the pulse, the temperature, and, perhaps the most important of all, the stage of the disease. Early operative interference will certainly reduce the percentage of mortality considerably. If the percentage of successful operations, as reported in literature, is still far from being satisfactory, it can be due only to disregard for this principle and to the fact that the unsuccessful cases are the result of a defect in diagnosis quite as much as in operative procedure.

In all of these cases the autopsy showed the presence of another abscess, so that the essential condition for success, a thorough evacuation, was not fulfilled. In six cases, besides subphrenic abscess, pyothorax was present. In nine cases abscesses were present in adjacent organs, *i.e.*, in the spleen, liver, kidney, etc. In four cases the additional disease was

suppurative peritonitis. In ten cases there was pneumonia, in addition to pyæmia, tuberculosis, actinomycosis of vertebræ, etc. In several cases an incision was made, but the abscess was not detected during life.

Varieties classified according to source.—By far the greater number of subphrenic abscesses are the result of pathological processes in the stomach. There may be direct perforation into the subphrenium, due to an ulcer or a neoplasm, or infection may occur through the lymphatics which drain that part of the stomach involved in the pathological process. Most of the cases reported, however, point to simple ulcerative processes as etiological factors.

The intestine is nowhere attached to the diaphragm. Consequently other conditions prevail here than in those organs which are in direct contact with the diaphragm. The experiments of Saenger very clearly illustrate the manner in which a subphrenic abscess may arise from the intestine. This author noticed that when he injected a solution of Berlin blue into the retrocæcal tissue, only a trifling amount of the colored solution could be driven around the cæcum and alongside the linea innominata down to the inguinal canal. But the liquid column rose behind the ascending colon, formed a considerable fluid collection around the right kidney, and, passing the inferior horizontal portion of the duodenum, reached the dull margin of the liver and the diaphragm. Little fluid reached the transverse mesocolon, and none at all the mesentery of the small intestine. From this experiment the rule may be deduced that subphrenic abscess is more apt to arise from perforation of the cæcum, ascending colon, or duodenum, than of the small intestine or transverse colon. The experience gained from autopsies is in entire accord with this theoretical assumption, as in thirty-two intestinal cases, reported by Maydl, perforation of the duodenum was found eight times; of the colon, four times; while perforation of the ileum was found only once, and that, too, near the colon. It is of interest to notice that the etiological factor of these perforations of the gut, with the exception of one case which was caused by a foreign body, were all ulcerative processes. Trauma could never be made out as a primary source. The ulcers of typhoid fever, since their favorite seat is the small intestine, cannot, according to Saenger's experiments, enter into the formation of subphrenic abscesses. Autopsies have shown that appendicitis causes subphrenic abscess by perforation from the appendix into the retroperitoneal space, the resulting abscess extending up behind the kidney and liver to the subphrenium. From the anatomical situation of the appendix, such abscesses are generally found on the right side, but in a few cases they have passed from behind the right kidney, over the vertebræ, to the left kidney.

The great advance in the therapy of appendicitis, however, leads us to hope that the future will give us very little opportunity to study its sequelæ at the autopsy table.

We seldom see a case of echinococcus in this country, but in Germany, Austria, France, and England, where it is more common, it sometimes figures as a cause of subphrenic abscess. Of the cases of subphrenic abscess due to this cause, seventeen were operated upon, with the result of seven deaths. No case recovered after perforation of the abscess into the pleura, except those treated by operative means.

The starting-point is generally an echinococcus cyst, formed in the cellular tissue between the diaphragm and the liver. Such a cyst may, however, be developed between the diaphragm and the left kidney or the spleen, since both these organs are occasionally the seat of the parasite, and are both in contact with the diaphragm. Simon-Brown, Mosler, and Fiaux have reported abscesses from this source.

In what manner subcutaneous trauma gives rise to the formation of subphrenic abscess is not always manifest. The explanation may be that trauma originally causes a simple extravasation, into which pus-producing organisms emigrate from the neighboring intestine. These microbes are usually abundant in the gut and are found in tissues whose vitality has been lowered by trauma, a most favorable soil for their further development.

It is also conceivable that trauma producing a capillary separation in the continuity of kidney, pancreas, or liver, causes oozing of the secretions of these organs, which may then irritate and infect the adjacent tissue. Or a more extensive rupture of one of these organs may cause the formation of an abscess within it, which later on might burst into the subphrenic space.

Sometimes trauma may be produced by an apparently insignificant amount of force. Simply lifting a heavy package, for instance, is reported to have done it. The literature contains seventeen cases with this etiology, six of them recovering after operation and two spontaneously.

The gall bladder and the intra- and extra-hepatic bile ducts naturally offer marked opportunities for the formation of subphrenic abscess. Bearing in mind that the anterior surface of the gall bladder adapts itself to the right inferior insertions of the diaphragm, it seems easy for inflammation of this organ to extend by means of the lymphatics, or by ulcerative perforation to the lower surface of the diaphragm. It may be that a stagnation in the flow of bile favors infection of the gall passages from the intestine. Retention cysts containing bile may originate in the liver itself as well as on its surface, and may burst and discharge into the subphrenum. Thus subphrenic abscess might arise from purulent cholecystitis terminating in ulceration and perforation, or from cholangiectasia due to obliteration of a large gall duct, or from cholangioitis terminating in purulent hepatitis, or from purulent inflammation of the ductus communis choledochus itself, followed by rupture.

There are reports of sixteen cases of cholangioitic origin (mine excepted). Of these, fourteen were not recognized until the autopsy, while two were operated upon successfully. In several of the cases gall stones were found. In all of them, naturally, the subphrenic abscess was located on the right side. Every one of the patients had complained of well-defined acute pain in the right hypochondrium.

The anatomical situation of the kidneys gives them an important relation to the formation of subphrenic abscess. According to Hyrtl's anatomy and to Maydl (Figs. 1 and 2), the kidneys are situated in the lumbar region of the abdominal cavity, and are covered in front by peritoneum. The right kidney lies in contact with the ascending, the left one with the descending, colon. Behind they are bounded by the lumbar region of the diaphragm, and above by the suprarenal capsules. The left kidney extends a little higher into the pleural domain, so to speak, than the right, so that in perforation from the renal sphere into the pleura, the left side is more frequently concerned than the right.

The most frequent cause of perinephritic abscess is a primary perinephritis, arising from a contusion in the renal region or from one of the infectious diseases. Another cause may be pyelonephritis calculosa, suppurativa, or tuberculosa. Repeated exposure to cold can scarcely be considered an etiological element.

Since suppurative pyelonephritis is most often the outcome of disease of the uropoietic apparatus, viz., prostatitis, stone, carcinoma of the bladder, etc., it will be wise to reflect upon the possibility of the formation of a subphrenic abscess in all such conditions.

The lower border of perinephritic subphrenic ab-

cess is generally formed by the ascending or descending colon, sometimes by the duodenum.

In reference to diagnosis, it is maintained that if the abscess occupies the whole anterior or posterior surface of the kidney, there is generally tenderness or pain, swelling, and œdema on the anterior surface of the abdomen. My own experience, however, does not accord with this, as, with the exception of pain, I found no local symptom in the case described below (Case II.), even seven weeks after the onset of the disease.

If the abscess has formed on the upper surface of the kidneys, pleuritic symptoms, combined with œdema of both legs, jaundice, ascites, and vomiting, may be observed.

Of eleven such cases reported in literature, only one was saved, the unfavorable course probably being due to delayed diagnosis. Perhaps, too, the kidney is so much affected in this condition that nephrectomy ought to be added to the operation for evacuation of the abscess.

Subphrenic abscess originating in the ribs (from a tuberculous focus, as a rule) is of rare occurrence. If situated on the right side it may easily be confounded with cholangioitic subphrenic abscess. In the cases reported in literature, the tuberculous process was localized, and there was consequently quick recovery.

The great tendency of subphrenic abscess to perforate into the thoracic cavity has been alluded to before. On the other hand, there are subphrenic abscesses of true thoracic origin. The most frequent purulent affections of the thoracic cavity are pyothorax and abscess of the lung. Suppurative pericarditis is rare. A circumscribed pyothorax may perforate directly, while abscess of the lung will first produce an inflammatory adhesion of the adjacent visceral and diaphragmatic pleura. Free pyothorax has a tendency to perforate the middle of the diaphragm.

Of nine cases reported in literature, one case recovered spontaneously by perforating into the gut; one after surgical operation; three died with, four without, surgical interference.

Metastasis is another important etiological factor, but is, as a rule, observed only in the tropics. It has been found after trauma in connection with pyæmia (septic phlegmon of forearm and tuberculous coxitis [Godlee]); following ulcerative processes in the digestive tract (perforation of fishbone into the vena portæ); and associated with fistula ani and gangrene of the appendix. Abscess of the spleen, perforating into the portal branches, as well as suppurative processes in the mesentery and mesenteric glands, may cause abscess of the liver. Malaria, enteritis, and dysentery may do the same. In tropical dysentery Koch¹ could always prove the presence of amœbæ in portions of the intestine, and regarded them as the etiological factor. Abscesses of the liver were also demonstrated by von Bergmann. Other authors claim that such amœbæ are not the cause of the abscess, but only the characteristic admixture of the secretion transported from the seat of ulceration to the liver.

An attempt was made to obtain cultures from the pus of thirteen cases of dysenteric abscess of the liver. In eight cases the results were negative. Among the positive results staphylococcus pyogenes aureus was found twice; staphylococcus albus, bacillus pyogenes foetidus and proteus, once each. But in sections and cover-glass preparations amœbæ were found in every one of twenty-two cases. In ten cases they were mixed with bacilli. Of eleven cases reported in literature, ten died. In one case recovery was obtained by surgical interference. Only two of the fatal cases were operated upon.

A wound inflicted directly in the diaphragmatic space may also in rare instances cause subphrenic

¹ Gaffky, "Reports on Investigations of Cholera," 1883.

abscess, somewhat as do the subcutaneous traumata defined above. The wound is generally produced by a bullet. There are in the literature reports of autopsies in four cases. The liver, kidneys, and thoracic cavity may be involved at the same time.

Besides the varieties described above, another group of subphrenic abscesses must be mentioned, the original sources of which either are questionable or cannot be discovered. There are eleven such cases reported in literature. In three of them successful operations were performed. One recovered after perforation into a bronchus. The other seven died under expectant treatment. In one case actinomycosis of the vertebra was found, while there was pyosalpinx in the case which finally perforated into a bronchus.

In those cases of subphrenic abscess originating in diseases of the female sexual organs, *e.g.*, endometritis, pyosalpinx, perimetritic exudations, the route to the subphrenium is through the retroperitoneal space.

Course.—As said above, subphrenic abscess may arise from infection carried from an area of suppuration by means of the lymphatics. It oftener originates in an abscess of an adjacent organ, which bursts into the subphrenium. The fistulous tract representing its route may then become obliterated, or may remain and gradually grow larger.

If perforation of a subphrenic abscess into a lung has taken place, the rusty sputa and their offensive odor, as well as that of the breath, together with the microscopical demonstration of elastic fibres, point to a limited gangrenous process as the initiative factor of the perforation.

The cough, which then is always present, generally brings up fetid pus, in which particles of food, such as starch grains or margarin crystals, can be seen by the naked eye or demonstrated by the microscope. This would, of course, point to a gastro-intestinal or cholangioitic source.

While in a small number of such cases recovery is obtained by the perforation, the majority of patients succumb either to the shock of the perforation itself, or to a foreign-body pneumonia later on. The symptoms of perforation into the pleura consist in intense pain, rapidly developing dyspnoea, and collapse; while those of perforation into the peritoneal cavity are identical with the well-known symptoms of the general type of peritoneal perforation.

Therapy.—The treatment of subphrenic abscess must be surgical. Before the days of asepsis, the surgeon very properly hesitated to open the chest or abdomen, but now such fear need no longer prevent him from procuring timely evacuation. Such evacuation can be thoroughly effected only by wide opening. This can usually be secured by resecting a piece of a rib, as the subphrenic abscess is generally within the extent of the ribs. Very exceptionally, it must be approached below the costal arches or the xiphoid process. I cannot agree with those authors who pronounce it a misfortune for the patient when the abscess is reached by the transpleural route. On the contrary, it seems to me that no other route offers so many advantages in after-treatment, as a rule.

While for purposes of prognosis it is important to know whether the pleura are adherent or present a cavity filled with serum or pus, so far as surgical procedures are concerned it makes very little difference. The adversaries of the transpleural route maintain that to open the pleural sac, if it be in a normal state, would expose it to the dangers of pneumothorax, as well as to infection from the atmosphere or from the escaping pus.

Regarding the first objection, pneumothorax, it has to be borne in mind that in subphrenic abscess the aspirating power of the diaphragm is greatly impaired. As is evident by the dullness on percussion, the dia-

phragm is pushed so far up toward the thoracic cavity as to be pressed against the thoracic walls to a considerable extent, and to have its summit brought into permanent contact with the costal pleura. It may even have been so overstretched as to be entirely paralyzed. Furthermore, the lower part of the thorax itself is generally expanded, thus diminishing its aspirating power. When pneumothorax does occur after the exposure of the pleural sac, and a feeble patient suffers shock, final incision and evacuation may be deferred until the following day.

In reference to atmospheric infection, I may refer to Petri's and Cleves-Symmer's experiments, which demonstrated bacteriologically what had long appeared probable from clinical observation, *viz.*, that the microbes contained in the atmosphere are non-pathogenic. Furthermore, I do not see why the pleura should be more inclined to become infected than other parts of the body, provided thorough aseptic prophylaxis has been observed.

While the incision should be made in the centre of the dull area, the exploratory needle will always indicate its ultimate route. The technique of the operation is practically the same as that of resection of a rib for pyothorax. As a rule, the eighth, ninth, or tenth rib is selected. I choose the median axillary line, as thence the thoracic walls can be reached equally well in front and behind. It also enables the patient to be brought to the edge of the table during the operation, and permits him to assume the dorsal decubitus; whereas, if the incision were made farther back, he would be obliged to lie on the healthy side, thus rendering evacuation more difficult.

It goes without saying that thorough aseptic precautions must be taken. Particular attention must be given to the skin of the patient and to the hands of the surgeon, scrubbing with green soap for three or four minutes, then washing with alcohol or ether, and subsequently with bichloride (1 to 500). To sterilize thoroughly the skin of the patient, it is advisable to cover the field of the operation for from ten to twenty hours with a large poultice of green soap, and allow this to remain until shortly before the operation. Should this tend to produce a dermatitis, a bichloride fomentation should be substituted. All the paraphernalia needed at the operation must, of course, be sterilized; the instruments, ligatures, etc., in boiling soda-solution, and the towels, sponges, etc., in steam. If no sterilizer be on hand, towels, sponges, etc., can also be sterilized in boiling water. The incision, about four inches in length, should be made directly down to the periosteum of the rib selected. Its direction must, of course, be parallel to the margin of the rib. An incision is then made along both borders of the rib, and the peritoneum both in front and behind is raised by means of an elevator.

FIG. 5.—Resection of Rib (rib riding on the elevator).

Having freed the peritoneum, the elevator is pushed beneath the rib, between it and its posterior periosteum, and allowed to rest on both edges of the wound (Fig. 5). With a blunt hook the tissues are retracted alongside the rib toward the axilla, and by means of

FIG. 6.—Thoracic Opening in Subphrenic Abscess.

the bone scissors the rib is then cut between hook and elevator. Next, the elevator is pushed toward the sternum, forcing the rib from the last fragment of adhering periosteum; the retractor is inserted into this end of the wound, and with the scissors the same manœuvre is executed. If my own elevator shears¹ are used, nothing is needed but to tear away the

connection between the periosteum and the rib and divide the rib, the instrument being of such shape as to keep the tissues properly retracted. One blade, if separated, can be used as an elevator, so that, with nothing else at hand than a knife and these shears, practically the whole operation could be performed. A piece two inches in length, or at least large enough to allow introduction of the finger, suffices for the purpose of drainage. It is impossible to strike the intercostal artery during these manipulations on account of its anatomical situation, while in performing simple incision this accident has frequently occurred (fatal hemorrhage was reported in Billroth's clinic).

A saturated solution of iodoform in ether is then spread upon the wound surface, to form a protection against the pus.

The very thin thoracic fascia and the costal pleura are now incised, and if the pleural sac be found empty the pus cavity is located by means of the exploring needle, and an opening is made through the diaphragmatic pleura just large enough to permit the introduction of a grooved director. As soon as pus appears in the groove of the director, a small Péan forceps is introduced and the opening gently dilated. Evacuation of the pus should take place slowly (it may consume twenty to thirty minutes). A sponge should be pressed against the opening from time to time to interrupt the stream, so as to avoid too rapid expansion of the lungs. If the condition of the patient permit the finger is now introduced and any solid masses, such as fibrinous lumps or necrosed tissue adhering to the abscess wall, are wiped out with the index finger or with a blunt spoon made for this purpose. For inspection, my dilating speculum² can sometimes be used to advantage. If hemorrhage should occur or if signs of shock are present, such procedures may be deferred for a day or two, as may also the irrigation of the cavity with a sterile normal salt solution, which is used to secure thorough evacuation. When malodorous pus is found, an antiseptic wash, preferably bichloride, 1 to 5,000, is used for this once, instead of the sterile salt solution.

The pleura or the edges of the diaphragm are stitched to the skin with four silk sutures (preferably iodoform silk), one at each end of the wound and one on each side, with strong Hagedorn needles. Thus the wound surface is entirely covered and the adjacent tissues protected against infection. At the same time secondary hemorrhage is prevented and the wound kept open. Then the cavity, if of small extent, is packed with iodoform gauze.

In real pyothorax about one ounce of an emulsion of iodoform glycerin (one-half ounce in children) is infused into the cavity as an antiseptic, as well as to reduce the amount of secretion. But if the cavity be very large a drainage tube, five-eighths to three-fourths of an inch in diameter, is introduced and secured by two large safety pins arranged in the shape of a cross. (In pyothorax I refrain from introducing it immediately after operation, for I have seen much hemorrhage follow its immediate introduction. No doubt the constant motion of respiration produces friction against the drain, which accentuates the irritation already produced by contact of the wound with the air; whereas, after the tissues have in a measure recovered from this shock and granulations have begun to form, *i.e.*, after about three days, a soft rubber drain is well borne.) The cavity is then covered with iodoform gauze. The whole side is protected with a large piece of pasteboard, which, after being slightly moistened, adapts itself to the contour of the body like a plaster-of-Paris dressing. A strip of rubber adhesive plaster serves to exclude the air. So the pasteboard during respiration acts like an aspirating valve and aids the absorption of the wound secretion at the same time.

Particularly in pyothorax, retention of pus is prevented if the patient always lies on the diseased side, and if his feet are elevated about every four hours to compel the pus to flow into the dressing. A pillow may also be pushed underneath the opening at the most dependent part. At a superficial glance this advice may appear rather strange, but clinical experience shows that the observance of this method is apt to prevent retention, and it is needless to urge the importance of never allowing stagnation of pus in a cavity. This also renders unnecessary the counter-openings advised by Kuester.

It is only after the rigorous procedures described above that the cavity can be pronounced entirely evacuated. No necessity of subsequent irrigation arises, which, besides being irritating, destroys those very adhesions much needed for the obliteration of the cavity. (How important these adhesions are for the agglutination of the pleura, for instance, was emphasized as early as 1865, by Dr. A. H. Smith, of this city.)

Two weeks after the operation a smaller and shorter drain is introduced. After another week this second tube must be shortened. When the discharge becomes serous and scanty the tube may be dispensed with, and a small strip of iodoform gauze or a wick substituted for a day or two. For the next few days the patient must be watched very carefully. The cavity may be obliterated after twenty-four hours, but very often the union is only superficial and retention of pus occurs, as shown by an elevation of temperature. In such case the drainage tube must be re-introduced and after a week its shortening repeated, until for about four days after the obliteration of the pus cavity no discharge appears and the temperature remains normal. In a doubtful case careful introduction of a grooved director through the scar tissue may reveal the presence of retained pus. The dressing should be changed twice a day for the first week; later on once a day, and after three weeks it will suffice to change the dressing every second, third, or fourth day.

The patient, if at all able, should get up after one week. During after-treatment, for the first few days small doses of morphine are administered for the purpose of immobilization. If the pulse be weak, strophanthus or caffeine may be added. Nourishment is given frequently and in small quantities to avoid overdistention of the stomach.

Full anæsthesia should be administered only if the pulse is strong. This is an exceptional circumstance in the case of abscesses that have existed for a long

¹ Osler, *Centralblatt für Bacteriologie*, Bd. 7, No. 23.

² Beck, "Modern Theory and Technique of Surgical Asepsis." Saunders, Phila., 1895, p. 213.

time. It is well known to what immense dangers a general anæsthetic exposes the thoracic organs when their functions are much impaired by compression. Ether being contraindicated in every respiratory disturbance, only chloroform could be used, and I need not call attention to the danger to which the use of

FIG. 7.—Anterior Resection in the Seventh Intercostal Space.

this paralyzing drug subjects the heart, which is always, in these cases, either displaced or somewhat compressed. Since the operation takes but a few moments, it would be better when an anæsthetic is required to use an ether spray. Even cocaine has its dangers.

If resection for subphrenic abscess is done anteriorly, an incision must be made from the anterior axillary line between the seventh and eighth rib (see Fig. 7). Having divided the fascia of the external oblique muscle, the seventh and eighth ribs are exposed and resected. The

further procedures are the same in this operation as described above.

The lumbar route (Fig. 8) merits special consideration in subphrenic abscesses of perinephritic origin. The incision in such cases should begin on the prominence of the sacro-lumbalis muscle and extend to the anterior axillary line. After the thick lumbo-dorsal fascia and the latissimus dorsi and serratus posticus inferior muscles are cut through, the sacro-lumbalis muscle is drawn toward the spinal column. The lumbo-costal fascia is next divided and the quadratus lumborum muscle appears running vertically, parallel to the border of the sacro-lumbalis muscle. A grooved director, introduced alongside the outer margin of this muscle, will lead to the pus cavity, which, after being carefully and slowly evacuated, must be packed with iodoform gauze. The after-treatment should be conducted according to the principles of aseptic open-wound treatment.

Histories.—A striking feature of the cases below is that they all concern the right side, and all occurred in men in the prime of life.

CASE I.—F. G., of this city, forty-three years of age, clerk. Family history good. On May 14, 1894, he was suddenly seized with violent pain in the right side radiating up to the axilla, nausea, and slight dyspnea. Under the application of an icebag and administration of codeine, Dr. L. Bischof, of this city, noticed marked improvement until four days later. Then the pain set in as violently as before. At the same time fever and slight jaundice developed.

When I saw the patient, May 21st, I found the following condition: Stout man (weight about 200 pounds), very restless and occasionally delirious. Hiccough. Temperature, 103.2 F.; pulse, 124; respiration, 26. Face icteric. Pupils of equal size, reacting well. The tongue thickly coated. Mucous membranes pale yellow. Percussion note normal on the left side; on the right side, dullness from the upper margin of the sixth rib to two inches below the costal arch in front, and clear sound from the middle of the scapula downward behind. Auscultation revealed vesicular breathing on the left and anteriorly on the right side. Posteriorly from the middle of the scapula, bronchial breathing. Below the eighth rib no respiration could be heard. Vocal fremitus normal.

Pulse small but regular. Abdomen distended and its walls tender. Percussion tympanitic. Urine scanty, containing no albumin. The patient had had no evacuation of the bowels for three days.

On account of the absence of previous respiratory symptoms, particularly of cough, the diagnosis of subphrenic abscess was made, its location as well as the jaundice pointing to a cholangioitic origin. The exploratory puncture, made in the anterior axillary line, seventh intercostal space, corroborated the diagnosis of abscess. Operation was refused, and death occurred four days later.

CASE II. (presented at the New York Post Graduate School, December 19, 1890, and at the Medical Society of the German Poliklinik, October 11, 1895).—F. B., of this city, forty-two years of age, grocer, married. Family history good. Father of five children: four of them are in good health; on the fifth I had performed resection for tuberculous hip. The patient had never been sick before. In September, 1889, he noticed a slight pain around the angle of the right scapula. One week later, about September 17th, he became feverish and the pain extended over the whole right side. No cough was present. The family physician called it pleuritis. Temporary improvement and normal temperature followed, as reported to me, alternating with attacks of fever and pain of varying intensity for fully seven weeks. During this period the patient was seen by many physicians, who variously pronounced the condition pleuritis, cholelithiasis, nephritis, carcinoma of the liver, carcinoma pylori, and muscular rheumatism.

On November 5th I saw the patient for the first time, and found the following condition: Emaciated man of medium stature; weight about ninety-five pounds. Face very pale. Appearance of a grave disease; so weak as to be scarcely able to move. Tongue shown with apparent difficulty. No swollen glands. Temperature, 100 F.; pulse, 116; respiration, 24. Percussion and auscultation revealed normal conditions on the left side (see Fig. 9). On the right side there were diminution of respiratory sounds and vocal fremitus below the margin of the eighth rib. In the posterior axillary line, there was dullness from the lower margin of the eighth rib to the upper margin of the third lumbar vertebra. In the posterior axillary line, roughened expiration. No râles, no cough, no expectoration. Heart normal. Pulse soft and regular. Right hypochondrium slightly more convex than the left. Dullness alongside the spinal column from the upper margin of the tenth rib and along the middle axillary line from the seventh intercostal space. Turning the patient made no change in the limit of the dull area. Anteriorly the liver overlapped the costal arch a little less than an inch. The right hypochondrium was painful to the touch. No tumor nor fluctuation could be felt. Constipation. Urine scant, containing no albumin but abundant sediment. No microscopical evidence of nephritis. Patellar reflex normal. No paresis. Slight hiccough.

Perinephritic abscess was suspected because of the

FIG. 8.—Lumbar Route. Incision passing under the Twelfth Rib.

pain in the right lumbar region, the remittent fever, and the extent of the dullness. An exploratory needle was introduced five times at different points of the dull area, with negative results. A sixth puncture, made

FIG. 9.—Dull Area. Slight Protrusion of Right Hypochondrium.

this time in the tenth intercostal space, brought out thick yellow pus.

The patient was immediately transferred to St. Mark's Hospital, where operation was performed the following day by making an incision alongside the outer margin of the sacro-lumbalis muscle. To get better access, the eleventh and twelfth ribs were resected without interfering with the pleura. On pushing a grooved director past the outer margin of the sacro-lumbalis muscle pus appeared. The opening was then dilated. After about half a pint of thick, cheesy pus had been discharged, the right kidney as well as the diaphragm could be inspected. The cavity was cleansed and packed with iodoform gauze. Uninterrupted recovery followed, and the patient was dismissed from the hospital five weeks after the operation.

CASE III. (presented to the German Medical Society of New York City, June, 1892).—A. M—, of South Carolina, thirty years of age, merchant, single. Family history good. The patient had never been sick before. In August, 1891, he was taken with repeated chills, disturbance of digestion, and emaciation. He was at first treated for malaria at his home. Later, when a slight cough set in, a diagnosis of pulmonary tuberculosis was made. As it was just at the time when Koch's tuberculin was being tried, the patient was sent to the institution of Dr. Aronson, of this city, to receive injections of tuberculin. Dr. Aronson, however, came to the conclusion that the patient suffered from abscess of the liver, and sent him to St. Mark's Hospital for surgical treatment.

On February 13, 1892, he presented the following condition: Emaciated man, of medium stature; weight about one hundred and twenty pounds; face and mucous membranes pale. Tongue thickly coated. Temperature, 101° F.; pulse, 120; respiration, 44. Profuse perspiration. Abundant expectoration. Sputa yellow and sometimes of a copper tint. Region of the liver painful to touch. Appetite poor. Considerable dyspnoea. Percussion and auscultation reveal normal conditions on the left side. Percussion on the right side showed complete dullness in front from the upper margin of the fourth rib to two inches below the costal arch (see Fig. 10). Posteriorly complete dullness

from the angle of the scapula to the lower margin of the tenth rib. Auscultation revealed râles from the clavicle down to the fourth intercostal space. Below this area there were no respiratory sounds at all. In the infraspinous fossa there were dry râles and amphoric breathing. No change in the limit of the dull area upon turning of the patient. Diminution of vocal fremitus on the right side. Urine scanty; no albumin. Constipation.

Operation under chloroform on February 10th, at St. Mark's Hospital. Typical resection of the eighth rib in the median axillary line. Evacuation of two and one-half pints of brown, cheesy, malodorous pus upon opening the pleural sac. To gain space a long piece of the ninth rib was resected.

Inspection of the immense cavity revealed a communication with the subphrenic space. Blunt dilatation brought out two ounces of the same kind of pus from this sinus. On irrigating the cavity with bichloride of mercury (1 to 10,000), great dyspnoea set in, the patient's face becoming cyanotic. After a violent fit of coughing the dyspnoic symptoms entirely disappeared, the patient improving very rapidly under the usual treatment; but whenever the cavity was irrigated the same phenomenon supervened. During the coughing brown sputa mixed with arterial blood were occasionally expectorated. This could leave no doubt as to the existence of a communication with the lungs.

Six months after the operation the patient had gained thirty pounds and was in excellent health. But a thoracic fistula remained; wherefore I resected six inches of the seventh and tenth ribs. The cavity then became much smaller, but the patient could not be persuaded to stay until perfectly recovered. Subsequently, however, as I am informed, recovery was complete.

A particularly interesting feature of this case is the question of the mode of perforation. It seems to me that the subphrenic abscess, most probably being of a cholangioitic origin, first perforated the lungs and then the pleural sac, whence it may have perforated the diaphragm a second time, thus forming a true "vicious circle."

CASE IV. (presented to the Medical Society of the German Poliklinik, June, 1895).—F. S—, of this city, thirty-one years of age, shipping-clerk, single. Family history good. According to Dr. E. Mayer, of

FIG. 10.—Case III. Dull Area.

this city, he was seized on March 24th with violent pain in the right side, nausea, and rapid pulse. These symptoms disappeared in two days under the administration of morphine. The diagnosis at that time was gall-stone colic. The patient resumed work for three weeks thereafter, when suddenly he was again seized

with intense pain of the same character in the same place. Temperature was about 101° F., but the pulse was very rapid. This time the pain persisted with varying intensity for ten days, when the patient was again able to attend to his business. Four days later the attack was repeated, this time dyspnœa being the predominant symptom.

On May 3, 1895, I found the following condition: Tall man, slightly emaciated; weight about one hundred and forty pounds. Face slightly yellowish-brown. Great dyspnœa (respiration, 64). Tongue thickly coated. No appetite. Right hypochondrium not protruding. No cough. Slight expectoration. Temperature, 99.5° F.; pulse, 126. Percussion in front revealed complete dullness, from the upper border of the fourth rib down to the line of the umbilicus (see Fig. 11). In the axillary line the same condition obtained. In the paravertebral line there was complete dullness, from the spine of the scapula down to the spinous process of the eleventh dorsal vertebra. Throughout the extent of the dullness there was no vocal fremitus. Percussion and auscultation from the fourth rib up to the supraclavicular region normal. Auscultation revealed vesicular breathing, rough expiration, and râles. The same condition behind. Amphoric and metallic sounds could not be made out. Whenever the patient was laid on the left side, a tympanitic sound took the place of the dullness from the upper margin of the ninth rib downward. Urine scanty, no albumin. Constipation: Considering the temperature, the great pain, the dullness, and the former history, the diagnosis of subphrenic abscess seemed justified. The subphrenic location of the abscess was rendered more probable by the entire absence of respiratory symptoms. The dyspnœa could easily be produced by the pressure of the accumulation. Exploratory puncture in the eighth intercostal space, in the posterior axillary line, revealed thick, brown pus. Bacteriological examination revealed diplococci which could not be defined. Cultures of proteus vulgaris, diplococcus citreus conglomeratus, and bacillus coli communis were obtained.

The patient was sent to St. Mark's Hospital, where the operation was performed on May 4th, under in-

gauze. Under the administration of stimulants the patient soon rallied, and on the following day, having used the aspirating needle as a guide, I introduced a grooved director through the diaphragm into the abscess and slowly dilated the opening. Red-brown clots and thick pus tinted with dark blood were evac-

FIG. 12.—Dull Area (posteriorly).

uated. The edges of the diaphragmatic incision were sewed to the skin. Typical dressing. Uninterrupted recovery. Discharged from the hospital cured, June 15, 1895. The microscopical examination yielded no information as to the origin of the abscess, but the clinical symptoms pointed to a cholangioitic source.

CASE V. (presented to the Medical Society of the German Poliklinik, October 18, 1895).—H. M.—, a Cuban, thirty-nine years of age, married, employed in the sugar business. On June 15, 1895, he was taken with diarrhœa, tenesmus, and pain in the epigastrium, with repeated chills. Later on, cough. At first the patient was told that he had malaria; later on, dysentery; and when the cough set in, pulmonary tuberculosis. At the beginning of July he removed to Jersey City Heights, where he improved slightly under anti-tuberculous treatment. On July 22d, Dr. Morvay-Rottenberg, of this city, diagnosed pyothorax, and sent the patient to St. Mark's Hospital for surgical treatment.

On July 24th, the following state was found: Emaciated individual, of phthisical appearance; weight about ninety pounds. Tongue thickly coated. No appetite; slight dyspnœa. Urine scanty; no albumin. Constipation. Temperature normal; pulse, 110; respiration, 42. The right hypochondrium did not protrude. Percussion in front revealed complete dullness from the lower margin of the third rib to one inch below the costal arch. Posteriorly (see Fig. 12) there was complete dullness from the third to the tenth intercostal space. The region in front, from the supraclavicular fossa down to the fourth intercostal space, was slightly tympanitic. The same behind from the supraspinous fossa to the third intercostal space. No respiratory sounds over the dull area. No change in the limit of the dull area from turning the patient. Râles from the supraclavicular fossa down to the third intercostal space. Cough and expectoration frequent. The yellow sputum did not contain tubercle bacilli. The exploring needle revealed thin, malodorous, yellowish-white pus, mixed with fibrinous flakes and gas.

FIG. 11—Case IV. Dull Area.

complete chloroform anaesthesia. After resection of the tenth rib the pleural cavity was opened. It was empty, and air rushed in with considerable noise. The face of the patient assumed a cadaveric appearance, and the pulse entirely disappeared. Fearing to proceed further, I packed the cavity with iodoform

Bacteriological examination showed the presence of bacillus coli communis, staphylococcus pyogenes aureus, bacillus pyogenes fœtidus, and proteus vulgaris. Taking into account the presence of respiratory disturbances, especially cough and expectoration, and the extent of the dull area, I diagnosed pyothorax.

On July 25th, resection of ninth rib in the median axillary line was made, under incomplete chloroform anæsthesia. The pleural sac was found empty. No pneumothorax. After careful introduction of the exploring needle through the diaphragm and gradual dilatation, a pint and a half of sero-pus was discharged. Typical dressing. Uninterrupted recovery. Discharged from the hospital cured, August 21, 1895.

AN UNUSUAL CASE OF GUNSHOT WOUND OF THE CERVICAL SPINE.

By ALFRED C. HAVEN, M.D.,

LAKE FOREST, ILL.

An interesting case of paralysis following a gunshot wound of the cervical spinal region recently occurred in my practice.

The first peculiarity was in its origin. Paradoxical though it may seem, the innocent cause of the disaster was our justice of the peace, who, filled with righteous indignation at the depredations of his neighbor's chickens, proceeded to administer summary justice to them without waiting for the minor technicalities of the law. Perhaps he knew too well these often block the course of justice.

His weapon was a navy revolver of 38 calibre. The second peculiarity now appears, viz.: One of the bullets missed the chickens, turned round the corner of an adjacent building, and hit my patient, one hundred yards distant, squarely in the neck.

As a possible explanation of this eccentric procedure, I might mention the justice suffers slightly with strabismus, or possibly the chicken may have been tough enough to deflect the bullet; but I realize modern medicine wants facts, not theory, so I will simply record the fact that the bullet described a very devious course.

And this brings us to the third peculiarity. The bullet penetrated the neck of my patient and he lived to receive the kindly ministrations of the justice, who, in lieu of a trained nurse, relinquished his judicial functions for those of a good Samaritan.

The accident happened August 9th, at 6:15 P.M. Patient, T. E.—, aged twenty. The ball entered the right side of the neck on a level with the upper border of the thyroid cartilage, immediately over the carotid artery, and I found and removed it from the opposite shoulder midway between the spine and the acromion, on the upper border of the trapezius muscle. He was unconscious of the wound, but complained of violent pains in all his extremities, requiring a hypodermic to relieve them. Strange to relate, the ball picked its way through the intricate anatomical structures of this region, without serious injury save to the spinal column; a body of one of the cervical vertebra evidently was penetrated or injured, as the subsequent symptoms proved. I found the entire left lower extremity cold and paralyzed; sensation slightly present. The right lower extremity was not paralyzed, but sensation was markedly diminished. The upper extremities were partially paralyzed in motion and sensation—total loss of power in left hand and partial loss in right. Continued sharp pains in all the limbs, and also in the intercostal nerves of the left side were present. Pain was felt along the whole spine to the cervical region. Paralysis of bladder existed.

Diagnosis.—I saw immediately that the ball had in-

jured the spine, and had produced either a fracture, with pressure on the cord, or else hemorrhage into the spinal canal, with consequent pressure. The neck could be moved freely without pain, and manipulation of the cervical spine gave no evidence of fracture, but the subsequent history of the case confirmed the diagnosis of blood clot.

The character of the symptoms located this to a certain extent. The motor paralysis was on the left side: the anterior roots of the spinal nerves on the left side were therefore pressed upon. After eliminating the effect of shock, which lasted a few hours, loss of sensation on both sides showed some pressure on the posterior roots of the spinal nerves, both right and left. There being little motor paralysis on the right side, showed the clot to be mostly on the left side of the canal, also extending somewhat backward, involving the posterior roots of the spinal nerves, as sensation was affected on both sides. The greatest pressure was in the lumbar region on the left side, involving the left anterior roots or motor nerves forming the sacral plexus, causing paralysis in the left leg. The subsequent history was as follows: August 10th and 11th, the pain persisted, requiring anodynes. August 12th, the pain in the left leg abated somewhat and was followed by numbness. Patient could distinguish different toes by touch; no motion. August 13th, less pain; urinated spontaneously for the first time since accident. August 14th, regaining sensation in right lower limb. The temperature was $101\frac{1}{2}^{\circ}$ F. the second night, but rapidly dropped and was normal the sixth day. The wound healed without suppuration in a week. Patient gradually improved till August 26th, when he was removed to St. Luke's Hospital, Chicago. His left leg was still totally paralyzed, his right lower extremity had regained sensation. Right hand still partly paralyzed, and unable still to use his left hand. I did not see patient again until October 21st, when he returned. I found that the arm and leg on the right side had regained both motion and sensation. Left arm improved, but could not flex or extend fingers. Left thigh showed muscular atrophy; could flex and extend both left leg and thigh, but had no control over muscles of foot and toes. In ten days the patient left for Idaho, where he soon got about on crutches. December 9th, when last heard from, he had abandoned his crutches and was getting about slowly, showing that the clot had been absorbed and function nearly restored, just four months after injury.

The case is remarkable, in that so large a bullet, 38 calibre, should perforate the neck with so little damage, and that a blood clot in the spinal canal should be absorbed and function so largely restored in so short an interval as four months.

The Poison of Viper's Blood.—Messrs. Phisalix and Bertrand, who have been studying the properties of viper's blood for some time, and who claim to have discovered that it contains the same poisonous substances as the venom of the same reptile, gave an account of additional investigations before a recent meeting of the Paris Academy of Sciences. They had supposed that the viper, which resists inoculations of its own venom, did so because it was accustomed to this poison. But they now find in the blood, besides the poisonous substance, another substance that neutralizes the effect of the former. These two substances are destroyed by heat at different temperatures. The toxic substance disappears if the blood be kept at a temperature of 58° C. during a quarter of an hour, while the antitoxic substance remains. If the blood thus heated be injected into a guinea-pig, not only does the animal not die but it can endure an inoculation of fresh viper's blood.—*Public Opinion.*

IS SYPHILIS ANTAGONISTIC TO TUBERCULOSIS?

BY FRANK W. ROSS, M.D.,

ELMIRA, NEW YORK,

ATTENDING PHYSICIAN TO THE ARNOT-OGDEN MEMORIAL HOSPITAL.

AN article by Dr. F. Abrahams of New York, in the issue of the *MEDICAL RECORD* for December 28, 1895, entitled "Syphilis vs. Tuberculosis," confirms an observation made by me several years past, but I have long looked for a second case of inoculation of pulmonary tuberculosis with syphilis.

My case began in 1886. A young man, about eighteen years of age, presented with incipient pulmonary tuberculosis and hemorrhages. A year spent in the pine woods of Michigan arrested the disease. He returned to me apparently well. About a year later he had a return of the hemorrhages, with cough, expectoration, night sweats, all the physical and rational signs and symptoms of pulmonary tuberculosis.

Although severely ill, he was decidedly amorous, and to my surprise he acquired a chancre of the glans and subsequently the secondary symptoms of syphilis developed.

This was in December, 1888. I was in despair, and expected a rapid increase in the pulmonary symptoms. I, however, placed him on iodides and inunctions of mercury, and to my surprise his pulmonary symptoms began to improve: his night sweats, cough, expectoration, and hemorrhages ceased gradually. He was under my eye for about a year and a half, with constant anti-syphilitic treatment. To-day, seven years after the initial lesion of syphilis, he is well and healthy. I frequently see him, acting as a delivery clerk for a grocery house, which requires constant work and exposure in all weathers, both night and day.

I have often wondered whether the cure was from syphilis, from the syphilitic treatment, or spontaneous. He had no other treatment, and is to-day well of both syphilis and tuberculosis.

My opinion has been, from a careful observation of this case, that the syphilis was antagonistic to the tuberculosis, but have in vain looked for a second case. Until Dr. Abraham's case I have seen none reported, and have failed to meet one in my own practice.

In view of some of the wonderful cures by serum-therapy, I am inclined to think that these two cases will furnish a hint, perhaps, for further investigation in this particular line. Doubtless such have been made, but I have never noted them.

The factors to note and questions to be solved are: Is syphilis antagonistic to tuberculosis? Is the ordinary treatment of syphilis in any way curative in tuberculosis? Or were the two cases noted merely a coincidence?

The Most Suitable Preparations of Digitalis.—In an article on "The Digitalis Group and Their Use," by Dr. George W. Balfour, of Edinburgh, he discusses the relative value of the different preparations of this drug. He says a word in the beginning with regard to strophanthus, which he considers is the only one of the digitalis group which has any pretensions to rival digitalis. It is so much more uncertain in its action, and so devoid of tonic qualities, that it will not, in his opinion, displace the old drug. Strophanthin, however, has two advantages over digitalin, namely, it is readily soluble in water, and is rapidly absorbed, and thus is of use when quick stimulant action is desired. The most suitable preparations of digitalis to employ, he says, are, first, the powdered leaves, carefully prepared, and not over a year old. The infusion ranks next to the powdered leaves.

A CLINICAL STUDY OF TRACHEOTOMY—TEN CASES, ONE DEATH.

BY FRANK V. CANTWELL, M.D.,

SURGEON TO ST. FRANCIS' HOSPITAL, TRENTON, N. J.

CASE I.—J. B——, man, aged sixty-five. Tracheotomy, low operation, before excision of tongue. Tube removed on second day, wound healed in a week.

CASE II.—M. M——, girl, aged two. Mother, in her efforts to remove a piece of a peanut that had lodged in the child's throat, pushed it into the wind-pipe. I was called by the attending physician on the second day. I found the child breathing rapidly with a wheezing sound, suffering for the want of sufficient air. Tracheotomy, low operation, done. Thymus very much in the way, pushing up into wound. Failed to find the cause of obstruction after many attempts. Breathing remained as it was. The tracheal wound was kept open. On the third day after operation, the child, who had been sleeping quietly, leaped to its feet, and after violent efforts, expelled what the nurse called "a lot of stuff," after which she obtained a great deal of relief. The peanut was no doubt among this stuff. The child is still well, although she is at times asthmatic.

CASE III.—G. W——, girl, aged six. Operation, September 12th; discharged well, September 28th. Tonsils covered with membrane, croup well marked, child very uneasy, breathing labored, cyanosis commencing. Tracheotomy, the low operation, was done. Antitoxin injected. Recovery uneventful.

CASE IV.—J. K——, boy, aged five. Operation, September 28th; discharged well, October 21st. This boy had nasal, pharyngeal, and laryngeal diphtheria. Croup marked, breathing labored, cyanosis. Tracheotomy, low operation, was done. Antitoxin injected. Membrane cleared off, and tube was removed on fifth day. On the seventh day I was called hurriedly. The croup had returned, and there was some membrane on tonsils again. With some difficulty I reintroduced the tube, and for several days, at intervals, casts of the bronchi were expelled. He was very much exhausted after this second attack, but was sent home well on the twenty-second day. While this boy was at the hospital, his brother died at home of diphtheritic croup.

CASE V.—S. E——, girl, aged two. Operation, October 31st; discharged well, November 10th. Laryngeal diphtheria. Croup marked, breathing labored, no cyanosis. Tracheotomy, low operation. Antitoxin given. Recovery uneventful.

CASE VI.—F. R——, boy, aged six. Operation, October 31st, at home; tube removed, November 5th. He had been sick for five days, with a few white spots on tonsils, and very slight croup. I was called by his medical attendant at midnight. The boy had grown rapidly worse. He was restless, uneasy, tossing, cyanosed, with rapid breathing and drawing in of epigastrium. Tracheotomy, low operation. No antitoxin. Recovery uneventful.

CASE VII.—J. M——, girl, aged eighteen months. Operation, November 15th; discharged well, December 10th. Some membrane on tonsils, croup marked, cyanosis, breathing labored. Tracheotomy, low operation. Antitoxin injected. It was with difficulty we introduced our smallest tube. This child got along well for several days, when it was noticed that milk escaped through the tracheal opening, due, I thought, to some paralysis. There was trouble in keeping the wound clean. Tube was removed on the seventh day, but had to be reintroduced on the eighth. There was some danger of septic pneumonia, but the child rallied, and was discharged well on the twenty-sixth day.

CASE VIII.—A. M——, girl, aged eight. Operation, November 4th; died November 5th. This child had

for several years a bad bronchial asthma. About two weeks before the attack of diphtheria she had measles, so that she was in no condition to withstand the disease that killed her. Tracheotomy, low operation, was done. Antitoxin was injected. About one and one-half drachms of pus, *débris*, and softened membrane were expelled upon opening the trachea. A like amount was coughed out after removing the tube the next day. She died thirty-six hours after the operation.

CASE IX.—M. McK.—, girl, aged six. Admitted, November 27th; operation, November 28th; discharged well, December 11th. She had some membrane on tonsils. Croup slight. Antitoxin was injected as soon as she came, with the hope that the membrane would not increase, and that the croup would be aborted. The child grew worse, until I did not feel that it was right to wait any longer. Tracheotomy, the low operation, was done, after which she had an uneventful recovery. I have succeeded in one instance in aborting a commencing croup by the use of antitoxin.

CASE X.—R. H.—, boy, aged four. Operation, November 29th; discharged well, December 10th. This child was a typical clinical picture of laryngeal diphtheria. He had what his physician called a relapse, croup coming on several days after the membrane had disappeared from his pharynx. Tracheotomy, low operation, was done, and antitoxin injected. He had the same trouble as Case VII. Milk, when swallowed, came through the tracheal opening. For a few days I was fearful of sepsis. Other than this, he had no bad symptoms, and was discharged well on the thirteenth day.

During this series of operations, four cases that refused operation died. In no case was tracheotomy refused. All of these children were suffering very much from mechanical obstruction before I saw them. Cases III., IV., V., VII., VIII., and X., were brought to the hospital in desperation, some of them driving a distance in an open carriage, wrapped in blankets. The low operation was done in the usual way, by careful dissection. In one case a small artery was cut, but required no ligature. In four of the cases a vein was tapped, flooding the wound with blood for a moment, but this was easily controlled.

After cutting the trachea a thread was passed through each edge of the opening, and loops made, about four inches long. This made easy the introduction of the tube, both at first and during the after-treatment. It also facilitated the thorough cleaning out of the trachea. As the incision was not long, no sutures were introduced. The usual gauze dressing was applied, although I have thought that gauze beneath the tube shield was in the way. I used tape long enough to go around the neck twice, so that it crossed at the back, and each tape could be pulled with equal force and tied on one side. I thus avoided any tilting of the tube on either side. The after-treatment was of the simplest kind. The tube was entirely removed every day and scrubbed. The inner tube was frequently taken out and cleaned. For this purpose I found very useful the small brushes used for cleaning the tubes of the old-style nursing-bottles.

Although the room was kept at a comfortable temperature, it was well ventilated. No effort was made to make the air moist. When the child's respiratory sounds were dry, or the breathing impeded, the trachea was steamed for a short time with lime-water or water with a pinch of bicarbonate of soda in it. The children were given milk for the first few days, and then ordinary solid diet. They were all very manageable, indeed; the insertion of a tracheotomy tube seemed to have a quieting effect, or else they appreciated what we were trying to do for them. I ascribe the good re-

sults in these cases to the use of antitoxin in conjunction with the low operation of tracheotomy. A strong argument with me is that before the introduction of antitoxin, I operated in six cases, with but one recovery. In Case VIII. there were undoubtedly other micro-organisms than the bacillus of diphtheria. It is just this kind of cases in which antitoxin is useless, cases in which there are not only pathological changes in the organs, but which are also inoculated with pyogenic organisms. Another argument in favor of the use of antitoxin is the fact that in not one of these cases of diphtheria was the wound infected, although no antiseptic was used, either as a wash or a dressing.

Progress of Medical Science.

Œdema without Albuminuria.—Dr. Tchirkaff calls attention to a new syndrome, characterized by great cedema without appreciable organic disease. He has studied six cases between 1886 and 1894. The patients were all men of from twenty-five to sixty years of age, generally of a good constitution, though some of them slightly anæmic. In the cases presenting anæmia the œdema developed slowly over a period of three to four months; in the plethoric subjects it developed much more rapidly. The anæmic cases strongly resembled the picture presented by cases of chronic nephritis. In the non-anæmic cases there was a different picture, anasarca coming on rapidly in the space of a week or so, the peritoneal cavity filling with fluid, and in the course of the next two weeks the pleural and pericardial cavities also showing signs of exudate. The face, trunk, and extremities all became swollen at the same time. At times only the upper extremities were œdematous, but usually the lower were most affected. In some cases the œdema affected mostly the neck, face, chest, and upper arms. Certain patients lost the hair from the eyebrows, beard, mustache, and pubes at the time that the œdema appeared; the hair of the head also became very thin and of a softer texture, and changed its color somewhat. The cases all ended in recovery. Most careful examinations showed that there was no nephritis in these cases: the urine was repeatedly examined, and albumin was never present, showing that they were not cases of chronic nephritis with temporary absence of albumin; there were never, moreover, any signs of uræmia or kindred symptoms. The blood was carefully examined in all cases, and no changes were found in either the number of corpuscles or the percentage of hæmoglobin; a large percentage of reduced hæmoglobin was, however, always present. The heart was negative in all cases, and there were no frank signs of hepatic cirrhosis. The majority of the patients either showed signs of or gave a history of a preceding lues. From the increase in the reduced hæmoglobin, and the fact that there were no signs of deficient oxygenation in the lungs or venous stasis, Tchirkaff concludes that we must be dealing with a stasis in the venules and capillaries, probably of vasomotor origin. As the result of his observations he formulates the following conclusions: 1. There exists a form of disease but little known, characterized by general œdema, with effusion into the serous cavities, without albuminuria; at the same time the heart, lungs, liver, and other organs show no change capable of causing œdema from blood stasis. 2. These œdemas are of a vasomotor origin and can be called "general vasomotor œdemas." 3. They are characterized by, and often accompanied by, dilatation of the right heart and moderate arteriosclerosis. 4. They are always accompanied by changes in the blood, *i.e.*, the hæmoglobin is considerably reduced. Beyond this one occasionally sees trophic trouble and pro-

nounced paralysis of the veins of the skin. 5. In most cases these œdemas are of syphilitic origin, and disappear under treatment by mercury and the iodides. It is possible that the œdema without albuminuria, from which the African soldiers suffer, does not always occur from cold or the formation of ptomaines from indigestion.—*American Journal of the Medical Sciences.*

The Diuretic Action of the Salts of Lithium.—As the result of an experimental investigation, which was confirmed by clinical observation, Mendelsohn has found that while all of the salts of lithium possess diuretic properties the most active in this direction is the citrate, which possesses the additional advantages of solubility and comparative freedom from unpleasantness of taste. Next in activity is the acetate. The author admits, however, that chemic solvents of uric acid are not necessarily useful agents in the treatment of gout or the uric-acid diathesis.—*Deutsche Medicinische Wochenschrift.*

Cure of Leprosy.—Dr. Goldschmidt, of Madeira, where more or less leprosy exists, reports in *Le Bulletin Médical* of December 18, 1895, a case of apparent cure after five years of treatment by frictions over the plaques and infiltrated areas with a five-per-cent. solution of pure eucrophen in olive oil. His conclusions are: 1. External applications of eucrophen oil should be recommended, in energetic and prolonged frictions, in all cases of leprosy of slight extent upon the skin surface and nasal mucous membrane. 2. Cases of internal leprosy or those in which the affection has invaded the entire cutaneous surface call for another mode of administration of the drug, namely, by subcutaneous injection of the same oil solution (sterilized and filtered). 3. Under the influence of this treatment the specific bacilli diminish or disappear; in consequence the propagation of the disease by contagion is rendered more difficult or impossible. Consequently preventive measures, such as segregation, can, at least in recent cases, be considered as unnecessary. The writer then gives an account of leprosy in the island of Madeira.

Schleich's Method of Local Anæsthetization.—The skin is first made aseptic, then pinched up and the sterilized needle of the syringe containing the solution, which should be cold, is passed obliquely under the epidermis, and a few drops are injected until a white elevated wale appears. The needle is withdrawn and inserted at the edge of this wale and so on until an area as large as may be desired is made anæsthetic. If the spot to be cut is first cooled by an ether or rhigolene spray, if it is the skin, and by a strong solution of carbolic acid, if it is the mucous membrane, the prick of the needle is not even felt, but in the case of the small needle, which should be used, the pain is almost nil, especially when the skin is pinched. Würdemann has used this method in operations about the eye and also in abscesses and felons with success. Schleich has even done coliotomies with it, but others might not dare follow this lead. The solution most usually employed is a grain and a half of cocaine, one-third of a grain of morphine, and three grains of sodium chloride in three ounces and three drachms of sterilized water. Two other solutions, one containing double the quantity of cocaine and the other one-tenth the amount, are also used. The value of this operation is in the technique, and stress is laid on the point that the needle must not go beneath the skin. This process is capable of development and is worthy of a careful trial.—*Maryland Medical Journal.*

Sex and the Prognosis in Epilepsy.—Dr. William Browning thinks that the prognosis for females, in epilepsy, is worse than that for males. Among twenty-

five males, he reports six definite and five presumptive cures. Among twenty-two females there was only one cure, and this was not a sure one. The statement that six out of twenty-five epileptics were cured would be received with considerable hesitation, and gives rise to some doubt as to the value of the observations, as a whole, though Dr. Gowers has stated that the prospect of an arrest in epilepsy is slightly better in males than in females.

A New Antiseptic—Loretin.—Dr. Herbert Snow, surgeon to the London Cancer Hospital, speaks in the highest terms of loretin as an antiseptic. It is an iodine compound, acid in nature, and forms compounds with sodium that are soluble in water. Dr. Snow says (*British Medical Journal*): "My own experience is confined to the powder, which I have never found occasion to mix with any other substance. Dusted on the skin, or over a granulated wound, this causes not the slightest irritation or unpleasant sensation. It immediately destroys the malodor of the most fœtid cancerous sore, controlling this in a manner which no other agent I have yet tried will do. Copiously puffed with an insufflator into the deep cavity formed by evacuating the axilla of carcinomatous glands, it efficiently precludes suppuration, even when free hemorrhage has taken place after the closing of the wound, an occurrence almost inseparable from anæsthetic vomiting when the patient has been removed from the operating table. Not the slightest bad symptom from its employment in this way has so far been detected. When there is no deep cavity a wound dusted with loretin heals rapidly by first intention. I have had recourse to loretin in some sixty cases, mainly operations on the breast and axilla, notoriously a test region for antiseptics. In my hands it has proved an ideal antiseptic and deodorant, with no single drawback; and I am sure that no surgeon who has once tried it will ever again resort to the noisome and toxic iodoform from the free use of which I have seen more than one death."

Membranous Colitis Treated by Colotomy.—Dr. W. Hale White and Mr. Golding Bird have reported to the Clinical Society of London the case of a neurotic woman of thirty who had suffered for ten years from membranous colitis. Colotomy was performed, and the bowel washed out. The discharges ceased, the wound was allowed to heal, and the patient was cured. Three months after her cure she died of general peritonitis.

"Consumptive Bowels" in Children.—Writing to the *British Medical Journal* on this subject, Dr. Hobson says that food has less to do with tuberculous infection than is generally supposed. Out of 70 children under five years old who died with more or less generalized tuberculosis at Guy's Hospital in ten years, in only 28 could the intestines or their glands have by any possibility been the primary seats, and in many of these other parts appeared jointly responsible for systemic infection. These 28 cases constituted barely 11.4 per cent. of the total cases of systemic infection of all ages during the same period, and of course a very much smaller percentage of the total cases of tuberculous disease. He would say that about 5 per cent. of all medical cases were under five years of age at Guy's. On further analyzing his notes, however, he finds that of 21 children under two years of age, 9 showed tubercle in the intestine or mesenteric glands which could not have come to them by way of the lungs, for in no case were any tuberculous masses breaking down. Yet in only 1 of the 21 cases were the lesions such as were at all likely to have given recognizable symptoms during life. In 12 cases the primary seats were elsewhere. The age period of ten

to twenty appears to furnish a larger proportion of abdominal to other tuberculosis than any other, for of 35 cases 16 came under that category. Out of a total of 246 of all ages, 70, or 28.4 per cent., were possibly abdominal in their origin. While no one can deny the great relative preponderance of abdominal tuberculous affection under five years of age, he for one does not admit that great preponderance which is assumed. Still less does he admit that this is a matter of feeding. For (1) the children of the people who seek hospital accommodation get very little milk, and (2) dirt swallowing is a potent factor which must not be overlooked. All little children, especially the poor, swallow much dirt. From the mouth, nose, and upper pharynx tuberculous organisms may find their way to cervical glands, as, it is true, may be also the case with food-remains in the mouth; or be carried down to the stomach when its secretion is alkaline, and thence travel safely to the intestines and glands. He thinks we must look not to food but to a greater vulnerability in the infantile alimentary tract for its greater proneness to tubercle.

The Local Action of Salol.—A recent paper by Dr. Colombini tells us that he has been experimenting with regard to the local effects of salol dissolved in liquid vaseline. In the presence of alkaline fluids or living tissues salol appears to break up into salicylic acid and phenol in the nascent state. When split up in this way the author found that, while the good antiseptic action of each of the acids was maintained, their irritant action was absent, either from the way in which they were set free or from the small quantities of the acids evolved. Clinically it was found that salol in vaseline solution—the best solvent—did not irritate the skin nor inflame ulcerated surfaces, which healed under the treatment without pain or local reaction. The author thinks there may be a useful field opened up in the local application of salol as a non-irritating and sufficiently powerful antiseptic.—*Riforma Medica*.

Affections of the Cerebellum.—Dr. Friedeberg has prepared a paper on the subject of cerebellar disease. His personal observations extended to 9 cases, but he also examines critically the experiments of Luciani. The author's 9 cases included 1 of glioma, 1 of angiosarcoma, 1 of cysticercus, 1 of massive tubercle, 1 of hemorrhage, and 3 of abscess. The details of the cases are shown in a very-instructive table. Etiologically, the disease could in no case be assigned to injury. In the 3 cases of cerebellar abscess there was middle-ear suppuration. The cerebellum is less frequently the site of abscess than the temporal lobe. In the case of hemorrhage there was arteriosclerosis of the cerebral vessels. The comparatively short duration of the disease was remarkable, the longest period being one year and a half, whereas the average was only a few months. The analysis of symptoms presented considerable agreement with Luciani's observations. In 8 cases occipital headache was present and in the remaining case of a child, aged three years, its presence could not be proved. It was mostly severe and usually the first symptom. In 5 out of these 8 cases there was marked rigidity of the neck, and this became more accentuated as the disease advanced. It was probably due to pressure on the medulla. Vomiting was present in 8 cases and vertigo in 4. Out of 8 cases long under observation there was more or less wasting in 5. Notwithstanding this dystrophy there were never any bedsores. Hemiplegic symptoms were never present. In cerebellar disease such symptoms hardly ever exist—at any rate, in tumor. The brachial monoplegia seen in 1 case and the facial paralysis in 2 cases were probably the result of pressure and not true cerebellar symptoms. Cerebellar

ataxia was seen in 2 cases only. According to Luciani, this ataxia is not the most characteristic symptom of cerebellar disease, as is believed by many. Forced posture was present in 1 case only. Here the patient lay with the body bent forward and the head backward. Forced movements were never present. Irritative symptoms such as spasm were seen in 4 cases, and were, perhaps, due to irritation of the mid-cerebellar peduncles. In 1 case the position of the hand was very like that seen in cervical hypertrophic pachymeningitis. In addition to the vomiting, probably due to pressure, the following symptoms were noted—loss of weight, occipital headache, vertigo, especially on standing and walking, ataxia, ultimate inability to stand or walk, spasm, etc. The rigidity of the neck was remarkable; it appears not to have been often noted. Of diagnostic value in abscess are the pain in the ear and tenderness over the mastoid process.—*Berliner klinische Wochenschrift*.

Extra-Uterine Pregnancy and Hæmatocele.—According to Dr. Condamin extra-uterine pregnancy is almost the sole cause of pelvic hæmatocele. The rupture of a tubal gestation cyst is far from invariably accompanied by the "cataclysm" and uncontrollable hemorrhage in which many authorities believe. Many such accidents have no symptoms, others give rise to small hæmatoceles, and only a few involve free loss of blood. Hemorrhages consecutive to ruptured tubal cysts in the first months of pregnancy cease spontaneously; operative measures are contraindicated at first, excepting when the rupture occurs after the fourth month, which Condamin believes is exceptional. The surgeon must wait till the collection of blood has become well encysted and the anæmic patient stronger. The best operation then is vaginal puncture and incision, with or without removal of diseased appendages. Abdominal section should be rejected in the majority of cases as more serious and less efficacious, as involving prolonged treatment, and as inducing grave complications in the future. Condamin describes three cases where the vaginal treatment was successfully employed. In one a piece of placenta, in two the fetus, was removed with the clots; in all more or less of the involved appendage was removed.—*Lyon Medical*.

Albuminuria During Pregnancy.—In a paper on this subject Dr. Harry G. Utley (*American Journal of Obstetrics*) says that albuminuria is simply an indicative symptom. Its meaning and import must be determined by the gravity of any coincident pathological renal condition (as shown by the urinary examination) and by the presence and degree of severity of the general manifestations of kidney disease. The treatment, therefore, is to be directed to the condition or set of conditions with which the albuminuria is connected or on which it is dependent, and its permanent disappearance will signify that the harmful processes or conditions with which it is related have become inoperative. Most naturally the therapeutic indications are suggested almost altogether by the condition of the kidney, the amount of elimination it can probably do, and the probable amount of noxious substances in the body to be eliminated, which latter condition can be made evident only by the signs of uræmic intoxication. In every instance it is wise to curtail the further production of toxin by restricting the amount of nitrogenized food. An exclusive diet of milk seems to fulfil the indications admirably, serving at the same time as a mild diuretic. The author has frequently seen albumin disappear altogether by the use of this measure alone. This result would seem to add some force to the proposition that albuminuria is often due to the presence and influence of these toxic materials. Excellent results may be gained by

employing a mixed diet of foods poor in nitrogen, viz.: bread, butter, fruits preserved or fresh, vegetables in limited quantities, etc., of which only a sufficient quantity to sustain nutrition should be taken, for any excess has to be eliminated by an already overworked kidney. This measure greatly relieves the kidney and puts it in a position to more effectually and quickly recover. Further, if circumstances demand or even justify it, the elimination of the harmful materials may be both hastened and accomplished by the use of the other emunctorial channels—the bowels and the skin. The indications for using one or both of these, as well as the degree to which their functions should be stimulated, must be suggested by the merits of each individual case. They should in all cases be kept active. The bowels may be “appealed to” with very satisfactory results by the frequent administration of the compound jalap powder, say in drachm doses every other morning, or any of the hydragogue cathartics, which will be found especially useful. As to the skin, its action may be encouraged by resorting to the hot bath, the steam bath, the hot-air bath, or the hot pack. The employment of the medicinal diaphoretics, especially pilocarpine, is not indicated except as a last resort, and even then the use of this agent should be extremely guarded, for the reason that pulmonary œdema is very often the result and the burden of cardiac depression is put upon the patient, possibly already struggling for life. It is probably neither wise nor necessary to unduly stimulate the skin function unless signs of beginning uræmia are evident, and even then their gravity should dictate both the method and the extent and frequency of its employment. The wisdom of the use of the stimulating diuretics to aid elimination by the kidneys is much to be questioned, at least in those cases not showing symptoms of uræmic intoxication, for it seems grossly unjust to goad on an already crippled organ when the same or a better result may be gained by the timely and judicious use of the eliminative powers of the bowels and skin. The high blood pressure incident to pregnancy cannot be overcome until delivery is accomplished; but it is not proposed to refer in this article to the indications for the inducement of premature delivery. The above principles of treatment, in addition to the fulfilment of any symptomatic indications that may arise, if prudently employed will bring much relief to the kidney laboring under untoward circumstances, and yield grateful and lasting satisfaction to the conscientious “man of medicine” in whose hands the destiny of so many innocent lives reposes.

The Intoxicating Principle in Alcoholic Beverages.—At a recent meeting of the Academy of Medicine, says the Paris correspondent of the *British Medical Journal*, M. Daremberg stated that pure alcohol at 10° is less toxic than impure alcohol, such as *eau de vie*, and above all old *eau de vie* made from wine at 10°. *Eau de vie* made from wine at 10° is less toxic than wine at 10°. *Eau de vie* is in fact wine purified. The intoxicating element in wine is not present in the part distilled, but in the residue. Red wine is more intoxicating than white wine; the latter is produced by the fermentation of the juice of grapes, whereas the red wine is the product of the fermentation of the juice, skin, and pips of grapes. It is the bitartrate of potassium which constitutes the special intoxicating principle of red wine. French beer contains five per cent. of alcohol; fifty cubic centimetres injected into the veins of a rabbit produced no result. The different varieties of cider, on the other hand, were generally very intoxicating. M. Daremberg injected alcohol into the veins of rabbits rendered tuberculous three days previously. Alcohol chemically pure did no harm, but *eau de vie* and wine killed them

rapidly. The wisdom of giving alcohol to tuberculous patients is therefore doubtful. The toxic quality of alcoholic drinks is not thoroughly evident when there is neither kidney nor liver trouble. Healthy subjects easily eliminate these toxic substances, which under certain circumstances may even be valuable as occasional stimulants.

Villous Tumor of the Rectum.—At a recent meeting of the Liverpool Medical Institution, as reported in *The Lancet*, Mr. Paul related the case of a woman, aged fifty-six years, from whom he had removed a very large villous papilloma of the rectum. Symptoms of bearing down, a constant desire to defecate, and the passage of blood and mucus had existed for five years. The growth formed a broad band two to three inches deep around the rectum about two inches and a half from the anus. The patient made a slow but otherwise good recovery. The tumor had the typical structure of villous papilloma and did not infiltrate the submucous tissue. The origin of the growth could be distinctly traced to the neck of Lieberkühn's follicles, and Mr. Paul suggested that the histological distinction between the three usual neoplasms in this situation was as follows: Papilloma commenced as an upward growth of the neck of the glands, polypoid adenoma as an overgrowth of the entire glands, and carcinoma as a downward growth of the deep portion of the follicles.

The Relation between Uric-Acid Excretion and Leucocytosis.—As the result of experimental and clinical observations, Dr. Kühnau has found that a group of diseases attended with leucocytosis are characterized also by increased excretion of uric acid, according to the *Medical News*. This increase is not to be attributed to the febrile process alone, as it may attend afebrile diseases (cachectic leucocytosis). Rapid subsidence of leucocytosis corresponds with increased elimination of urates. Experimental leucocytosis is attended with increased elimination of urates, which reaches its maximum with the disappearance of the leucocytosis. Increased excretion of uric acid may be induced without the intermediation of leucocytosis by the administration of substances rich in colorless blood-cells (aseptic pus, thymus infusion). Injections of nuclein induce directly increased elimination of urates, for which the leucocytosis developed at the same time cannot be held responsible. Colorless blood-cells constitute, if not the exclusive, the most important source of uric acid.

Post-Mortem Cæsarean Section.—Hoffman reports the case of a woman seized with eclampsia in the eighth month of her fourth pregnancy. Death ensued in the course of two and one-half hours. Cæsarean section was performed ten minutes after the last inspiration, resulting in the delivery of a living male child fifteen inches in length. Nourishment was administered to the child by means of a spoon, but in consequence of enfeebled vitality it died at the end of twenty-five hours.—*Centralbl. für Gynäkologie*, 1895, No. 50, p. 1,319.

Splenic Tissue and Bone Marrow for Malarial Cachexia.—Critzmann administered daily more than an ounce and a half of the finely chopped spleen of a young beef mixed with two drachms and a half of bone marrow and the yolk of an egg. Cases of chronic malarial cachexia presenting anæmia, emaciation, and enlargement of the spleen, in which the usual remedies, quinine, arsenic, hydrotherapy, etc., had failed, were greatly benefited when treated in accordance with the above method for several weeks.—*Revue de Médecine et de Chirurgie*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 15, 1896.

PHOTOGRAPHING THE INVISIBLE.

THE great interest in Roentgen's discovery of photographing the invisible is still unabated. The entire scientific world is busy in developing the wonderful process and in devising means for the practical application of its principles. In the present issue we reproduce a beautifully finished photograph, taken by Professor Roentgen, which shows in a very satisfactory manner what can be done with the detail representation of the living hand by means of the cathode rays. This is one of the latest authentic photographs taken by the distinguished scientist and one of the most recent that has reached this side of the Atlantic. It was kindly forwarded to us by our correspondent at Berlin, and for perfection of finish and accuracy of detail can be viewed not only as a scientific curiosity but as demonstrative of possibilities in the direction of extended usefulness in surgical diagnosis and pathological demonstration. Contrary to the many exaggerated representations of such conditions by the daily press, in which even the common anatomical details are inaccurate and absurd, this picture carries on its face the real evidences of genuineness and commends itself to thoughtful anatomical study.

The phalanges and metacarpal bones are shown with surprising distinctness of substance and outline, while the positions of the sesamoids and of the bones of the carpus are well indicated. The trapezium, scaphoid, os magnum, unciform, and the projection of the pisiform can be differentiated, while the trapezoid and semilunar are somewhat blurred as to definition. The same may be said of the articular extremities of the radius and ulna, which are evidently not in focus. The fleshy parts are well represented, while the finger ring, presumably of gold, is most distinct of all.

By the careful inspection of the skeleton hand, as a whole, many of the possible lesions of the bony tissue of such parts of the body as may be subjected to the Roentgen rays can be believed possible of demonstration, and be easily understood. An impacted bullet, the line of a fracture, the position and dimensions of a bony tumor, the existence of a sequestrum, or, in fact, any other similar pathological condition of bone, can probably be shown as clearly as is the ring upon the finger. Indeed, most of these conditions have been already demonstrated, with the promise of still more wonderful revelations.

Thus may we not hope, with the perfection of methods, that all the hitherto hidden recesses of the body may yet yield their tribute to the new light and open to view many, if not all, of the abnormal processes of the living body, as effectually as does the post-mortem knife in the hands of the most skilful pathologist? There is no doubt, in view of the present extensive experimentation, that the apparatus by which these results are obtained will soon become simplified, so as to place its range of application within the reach of the ordinary medical photographer. It has already been asserted that a Roentgen tube can be constructed by the multiplication of ordinary incandescent light bulbs having interrupted circuits. Aside from the use of these "X" rays in photography, it has been suggested by Mr. Glover Lyon, a correspondent in a recent issue of *The Lancet* (February 1st), that they may be utilized in the destruction of germs inside the body, and notably in connection with the well-known germicidal power of violet rays. Who knows? We may yet be able to throw a new light on the tubercle bacillus and give renewed hope to the forlorn consumptive, ever vainly waiting for a new remedy.

THE MECHANISM OF CEREBRAL CONCUSSION.

THE mechanism of shock, cerebral concussion, and cerebral traumatism, is a subject that is still much discussed, and there is as yet no satisfactory explanation or agreement as to the method by which severe blows upon the head produce their effects. The clinical facts are simple enough. We know that when a person receives a severe blow on the head, he falls down unconscious, his muscles relax, the reflexes are abolished, respiration is shallow and slow or irregular, and the pulse is weak and easily compressible. From this condition he may gradually rouse, or he may remain in a comatose state for a considerable time. Post-mortem examination, if the patient dies, sometimes reveals lesions and sometimes does not. There may be a superficial blood clot or localized bruising of the cortex. In some cases there are multiple punctate hemorrhages. In other cases there is a congestion.

Dr. S. P. Kramer, in the *Annals of Surgery*, has recently contributed a series of experiments tending to elucidate the condition which we have above described. Dr. Kramer precedes a description of his own experiments with a brief *résumé* of previous opinions upon this subject. He shows, as we believe others have already shown, that Durét's theory of concussion, according to which the effects are due to driving the cephalo-rachidian fluid through the foramen of Magendie into the fourth and other ventricles, is neither satisfactory nor rational. Koch and Filehne produced the symptoms of concussion in animals by striking the skulls with a hammer weighing from a half to about one pound. The blows were not severe but were continuous, the result being that after a time a concussion was produced which simulated that caused by a single severe blow. Their explanation of this was that the unconsciousness and practical suspension

of brain functions was due to a mechanical over-stimulation of the brain, just as nerves may be paralyzed by a continuous over-stimulation. Stromeyer held that the blow depressed the skull and produced a momentary increase of intracranial pressure which cut off the blood supply and thereby led to suspension of brain function. Dr. Kramer, who manifestly leans toward this view, instituted a series of experiments upon dogs in order to test its validity. By means of suitable apparatus he was able to record the condition of blood pressure, respiration, and intracranial tension when the blow was being applied. The record of intracranial tension was obtained by fastening a metal tube into a trephine hole in the parietal bone. This tube was filled with physiological salt solution and connected with a Marey writing tambour. Dr. Kramer's experiments showed that when a blow was applied to the skull there was at once suspension or a delaying of respiration. If this respiratory paralysis became permanent of course the animal died, and it is by this sudden respiratory paralysis that some cases of instant death from a severe blow on the head might be explained. The effect of a blow upon the cardiac rhythm was less marked. The blood pressure was slightly lowered in severe concussion. In some cases there was no change in the cardiac rhythm. As regards intracranial tension, he found that the blow always produced a sudden increase. He regards it, therefore, as proven that this sudden and temporary increase in the intracranial tension is always produced by a blow severe enough to cause any cerebral disturbance. He then attempts to explain how it produces this disturbance. In brief his theory is that the blow on the head produces a compression of the brain, as a whole. This compression causes an interference with the blood supply, which leads to a sudden cerebral anemia, and this accounts for the primary symptoms of cerebral concussion. The subsequent symptoms depend upon the amount of damage done to the brain and the blood-vessels, the amount of hemorrhage, and so forth. He thinks that the capillary hemorrhages and bruising are due to the sudden driving of the brain against the rigid skull. Dr. Kramer does not think it necessary to add in further explanation the theory of Kocher, who maintains that the blow on the head acts as a crushing power and leads to a mechanical microscopic bruising of the brain substance.

It seems to us that the compression theory alone, however, is not adequate for the explanation of all these symptoms of cerebral concussion, for, if they were due to sudden anemia alone, the brain would very quickly recover its normal condition. As a matter of fact we know that after cerebral concussion there often remains a long period of disturbance, and we have a right to assume that this occurs even when there are no decided bruising or superficial bruises or hemorrhages. The fact that occasionally there develop in later years peculiar mental disturbances, such as epilepsy and sclerosis, would favor the view of Kocher, that there is, at least in the severer concussions, a microscopic laceration of brain tissue and blood-vessels.

Dr. Kramer has evidently not seen the monograph upon this same subject by Dr. J. Braquehay (*Archives*

Générales de Médecine). This physician made experiments of very much the same character as those of Dr. Kramer and attained results which are detailed with much elaboration. They do not, however, conflict with the actual experimental findings of Dr. Kramer.

RATIONAL TREATMENT OF ABORTION.

DR. BENICKE has just published a comprehensive paper on this subject based on a large number of personal observations. He claims very good results from the treatment, which is strictly in accordance with modern views of asepsis. He believes in being "meddlesome" at the proper time. We append a *résumé* of his conclusions taken from the *Allgemeine medicinische Central Zeitung*, December 21, 1895.

1. In cases of severe hemorrhage and febrile disturbances occurring in the first two months the entire contents of the uterus should be removed. The finger or the curette or both may be used for this purpose. The calibre of the cervix will determine the choice of method.

2. In the third month, if the os uteri is not patent, tampons are at first employed. Anæsthesia is necessary for the radical removal of the product of conception. The placenta may have to be removed by means of the curette. The fœtus can generally be best taken away by slowly introducing the finger and using that alone.

3. In the fourth month the fœtus must be removed without the aid of the curette, although remnants of placental structure and membranes may call for the use of that instrument.

4. Even after spontaneous abortion the uterine cavity is to be explored and all remnants promptly removed by means of the curette.

5. Only very free hemorrhage calls for the employment of tampons. They are to be introduced into the vagina only. Uterine tampons are to be avoided as much as possible.

These views are not particularly novel, nor very radical, but they bear examination as embodying the results of large and conservative practice by a modern accoucheur.

IS THE HUMAN RACE DETERIORATING?

THE February number of the *North American Review* contains an article upon this subject which is rich in statistical lore. Out of it we extract some facts that are of interest to medical readers. The author shows by the statistics of births, deaths, and marriages of the seven principal European nations that the birth rates in these nations have declined, notably since 1880, but that the death rate has declined still more, so that the surplus of births over deaths is rising. It is also shown that marriage-rates have declined since 1880 but that the number of children to a marriage has increased, and that the natural increase of population has proceeded with greater rapidity in the last ten years than it did before. He

also shows that in the United States there has been a steady decline in the rate of increase of population, but that the annual increase of American-born population has been a uniform one up to the last decade, when it fell to $17\frac{1}{2}$ per thousand. This declining ratio has been coincident with a very great increase of the city population and a decrease in the relative number of children. One striking fact is brought out, namely, that in the United States there are more children per thousand inhabitants than in any European country; thus the number of persons under 15 years of age per thousand inhabitants in this country is 368, while in France, which furnishes the other extreme, it is only 266. Still another fact, which is not of so pleasant a character, is that the span of life in the United States is shorter than in Europe. Comparatively few people in the United States pass the age of 60. Thus, the number of persons 60 years or more of age among 1,000 persons over 20 years of age is in the United States 107, while in England it is 134, and in Ireland 196. It seems, therefore, that in the United States the rate of increase in population is diminishing, that the number of children per thousand is greater than in any other country but is decreasing, and that old age is not so often reached as in other lands.

The writer does not attempt to give explanations for these conditions. His general conclusion is, however, that the human race is not deteriorating, because it is increasing in numbers. It does not seem to us that this is an absolutely trustworthy criterion for testing the vitality of a race, although, so far as it goes, it is no doubt an encouraging sign.

DOCTORS AND THE BRITISH ARMY.

ANOTHER example has been reported of the way in which British army surgeons are treated by the officials of their department. Surgeon John Fowler, captain in the British army, was detailed for duty with a regiment, and he one day happened to witness an act of gross indecency in which several of the younger officers were implicated. Dr. Fowler protested against it and induced them to stop. He did not, however, report the occurrence, because his senior captain had also witnessed it and it was his business to report it. Moreover, as a medical officer, he had nothing to do with discipline outside his own department. A court of inquiry was ordered, and Dr. Fowler was dismissed from the service by peremptory order. Curiously enough, the name of the senior captain who was also present was not mentioned, and he escaped scot free. The captain later admitted that he was present and he was dismissed from the service. The doctor repeatedly applied for a court martial, but that was denied him. The state of the matter seems to be this: That a surgeon who had served for ten years with great credit in the British army was dismissed from his service without any trial for not having acted as an informer, when it was not, in any sense, his duty to be such.

News of the Week.

The New Medical Specialty.—Bicycling on the Boulevard is now extensively practised in the many leisure hours at the disposal of the "busy" practitioners of this city.

The Association of Assistant Physicians to Hospitals for the insane was organized somewhat less than a year ago, and has held two meetings, one at Kankakee and one at Kalamazoo. A third meeting will be held at Independence, Iowa, during May, 1896. Dr. I. W. Neff is secretary.

The St. Louis daily papers have been raising a sensation, says the *General Practitioner*, over the fact that two St. Louis surgeons made a mistake in diagnosis, and opened the abdomen of a pregnant woman, in whom they had expected to find a malignant tumor. There were some extenuating circumstances in the fact that the woman was of unsound mind and unmarried, and, therefore, neither the symptoms that she gave, nor the facts surrounding the case, led them to anticipate such a development.

New Hospital at Carlisle, Pa.—The new hospital presented to the city of Carlisle by the widow of the late ex-Congressman Lemuel Todd was dedicated on January 29th, President George E. Reed, of Dickinson College, accepting the gift in a brilliant speech.

Tea Smoking.—Cigarettes made of tea are said to be extensively smoked by fashionable women in England and to be responsible for many nervous maladies.

Explosion in a Hospital.—By the explosion of a barrel of alcohol on January 28th, the Jefferson Medical College Hospital suffered slight damage, though what might have been a frightful calamity was narrowly averted. There was a small panic among the patients, although it is not known that any were seriously harmed. The boy to whose carelessness the accident was due was rather severely burned.

Metropolitan Medical Society.—At a meeting of the Metropolitan Medical Society, held January 28, 1896, the following gentlemen were elected officers for the coming year: Dr. E. L. Meierhof, *President*; Dr. M. S. Kakels, *Vice-President*; Dr. I. P. Oberndorfer, *Treasurer*; Dr. Percy Fridenberg, *Recording Secretary*; Dr. L. M. Michaelis, *Corresponding Secretary*.

The Atlantic County (N. J.) Medical Association held its sixteenth annual meeting in Atlantic City on February 5th and elected the following officers: *President*, Dr. Philip Marvel; *Vice-President*, Dr. W. Blair Stewart; *Secretary and Treasurer*, Dr. Talbot Reed; *Reporter*, Dr. Walter Reynolds.

To Abolish the Office of Coroner.—A bill has been prepared under the auspices of the Medical Society of the State of New York abolishing the office of coroner when the present terms of those holding the office shall have expired. It will be presented to the State legislature without delay, and provides for the appointment by the appellate divisions of the Supreme Court of medical examiners and assistant medical ex-

aminers, four in each class, two of whom shall be an expert pathologist and an expert chemist respectively. The salaries of the principals are not to exceed \$5,000 yearly, paid by the State, while the counties in the different appellate divisions of the Supreme Court throughout the State pay the assistant examiners. The examiners and their assistants are to have all the power and privileges which are granted to the present coroners.

The Eastern Medical Society of New York.—On Friday, February 7th, Dr. S. Brothers read a paper on "Hypnotism," which was discussed by Drs. F. C. Valentine, L. Fischer, L. Lichtschein, R. G. Wiener, C. Block, and others.

New York Post-Graduate Medical School and Hospital.—Dr. Louis Fischer has resigned his positions as instructor in diseases of children and attending physician in that institution.

University of Pennsylvania.—Dr. Morris J. Lewis, a well-known physician and son of the late treasurer of the University of Pennsylvania, has been elected a trustee of the university to fill a vacancy caused by the resignation of Dr. William Hunt, who is in precarious health.

Jefferson Medical College.—Dr. George Dock, of the University of Michigan, has declined the chair of pathology and bacteriology in Jefferson Medical College, to which he was recently elected.

Dr. Horatio C. Wood, who suffered a fall from his bicycle a short time ago, has, upon the advice of his physician, gone South for rest and recreation.

State Hospital for the Insane at Norristown.—Drs. John R. Deaver, E. W. Holmes, Orville Horwitz, and Edward Martin have been elected members of the consulting surgical staff of the State Hospital for the Insane at Norristown.

The Prince and the Malaria.—The English journals come to us with accounts of the last illness and death of Prince Henry of Battenberg. This gentleman, whose life seems to have been far from a happy one, set out with the Ashanti expedition, and while there contracted a malignant form of malarial fever, from which he died. The *Medical Press* says, in a somewhat cold-blooded way, that "one good result that may accrue from the lamented death of Prince Henry is the more careful study that the subject of malaria will probably receive." It seems to be intimated that, while Prince Henry living was of no particular use, Prince Henry dead lends himself greatly to the advancement of pathology and the promotion of malarial therapeutics. Already one article has appeared, in which it is stated that the use of five grains of quinine daily by persons who are in a malarial region will keep off the disease. This does not seem to be a sufficiently epoch-making discovery to balance in any wise the untimely death of an esteemed person. But it may be only a beginning.

A Surgeon-General of the Cuban Army is reported to have recently arrived in this country.

Professor Du Bois-Reymond, the physiologist, who is now seventy-seven years old, is about to resign his office of perpetual secretary of the Berlin Academy of Sciences.

New Health Bill for South Carolina.—A bill has been introduced in the general assembly of South Carolina providing for the reorganization of the health law of that State. Two additional members are to be added to the executive committee of the State board, viz., the chairmen of the medical committees of the house and senate respectively. Five reputable physicians in each county, appointed by county societies or by the governor, are to constitute the county health boards. Each county officer residing in different townships shall be president of a local board consisting of himself and two other members, who shall be physicians by preference. It is also provided that these boards shall superintend and direct the collection of vital statistics, prevent and arrest contagious diseases, and in all other respects enforce necessary sanitary regulations.

The Kitasato Serum.—The Japanese mail brings by way of Vancouver the report of great excitement in medical circles, due to the announcement by Dr. Kitasato that he has produced a serum capable of arresting the plague, curing diphtheria, arresting cholera, and neutralizing the effect of the bacillus lepræ. The discoverer's great reputation gives much weight to the claim among Japan's physicians.

Too Presumptuous by Far was the throwing out of a bid for \$10,000,000 of the new bond issue because made by a physician. Just as if the profession were not filled with men well able to take up a few millions in bonds with their surplus earnings, if they have a mind so to do!

A Medical Man on the Board.—Dr. Alexander Hadden has been elected a member of the board of directors of the New York Juvenile Asylum. This is a new and desirable departure, and the office falls to a thoroughly representative and capable man.

Alleged Discovery of a Cure for Leprosy.—The government of the United States of Colombia has ordered that the lepers throughout that republic shall be treated by the new method discovered by Dr. Carsaquila, of Bogota.

The New York Orthopædic Hospital authorities have purchased the building adjoining and the hospital will be enlarged.

A Memorial Tablet to Surgeon Parke.—Stanley and Mounteney Jephson, the only white survivors of the Emin Pasha relief expedition, have just erected a brass tablet in Kilmore Church to the memory of their comrade, Surgeon Parke.

Misused Prescription Blanks.—There is a man about town who takes prescription blanks with name and address of physicians printed thereon, and, forging an order for sample drugs, acts as messenger for the physician and appropriates the package. Several drug firms, especially such as deal in tonic wines, have been victimized.

The Late Dr. Edward Wigglesworth, of Boston.—The *Boston Medical and Surgical Journal* offers the following eloquent tribute to the character of the distinguished pioneer dermatologist of America: "Throughout this period of continuous productive activity there was but little medical work of general public importance to this community in which he was not a participant. His enthusiastic, costly, although somewhat premature, labors in behalf of the popularizing of the metric system are well known. More fruitful were his efforts in establishing the Boston Medical Library Association, of the executive committee of which he has remained a member from the outset. He did yeoman's service as one of the committee to raise the large sum of money necessary to establish the Harvard Medical School in its present admirable building. He was an active participant in the early attempts at securing the registration of physicians, that the citizens of this State might be protected against quackery and extortion. As a member of the health Department of the American Social Science Association, he spent years of faithful and persistent effort in promoting its unselfish objects. Without undertaking to enumerate the entire list of public obligations he assumed, it suffices to state that he was always ready to encourage by word and deed, by suggestion, advice, and gift of money, all worthy objects demanding the active interest of the public-spirited physician; and his assistance was usually sought both in the inception and in the promotion of such objects. To what extent his private beneficence may have reached, none know but those who have profited from it. That it was abundant there is no doubt, but what his right hand did his left knew not. Through inheritance able to live solely for his own pleasure, his life was one of continued devotion to the welfare of others. A hater of shams, he was fearless in their denunciation. Uncomprising in his own sense of right, he always recognized that the golden shield might have a silver lining, and, therefore, was tolerant of the views of others. With the highest ideals, his life was a constant struggle in his efforts to live up to them, for, from the vividness of his imagination, possibilities often had to him the force of probabilities. He shone among his friends, to whom his brilliant wit was a never-failing source of delight, and the sparkle of his conversation made his seat the head of the table. To them he was ever loyal, trustful, chivalrous, tender in sorrow, courageous in danger, and to them who thus knew him through many years his memory will remain always green."

To Keep Horses from Balling.—Many of our readers, compelled at this season to drive over snowy roads, will be glad to learn that when glycerin is applied to the soles of the horses' hoofs "balling" is effectually prevented.

Proposed Medical Laws for Mississippi.—Bills have been introduced into the State legislature of Mississippi providing for the creation of an executive committee of the State Board of Health which shall control the licensing of medical practitioners; for the imposition of a yearly tax of \$10 on all legally

qualified practitioners, and also for preventing pharmacists in towns of over two thousand inhabitants from practising medicine. The inference from the latter would be that the inhabitants of small towns must be satisfied with what they can get in the way of medical advice.

A Curious Accident.—A woman in Elizabeth coughed up a wisdom tooth which had been lodged for three months in one of her bronchial tubes, and which had found its way there immediately after it was extracted and while she was under the influence of nitrous oxide gas. The name of the careless dentist is, fortunately for him, not given.

Trouble at the Hebrew Sheltering Guardian Society Orphan Asylum.—This institution, containing nearly eight hundred children, situated at 151st Street and Eleventh Avenue, has just been quarantined by the health department. The attending physician and consulting staff have resigned, for the alleged reason that the managers declined to follow suggestions regarding the necessary isolation of patients. According to the last monthly medical report made to the health department by the late attending physician, there were three hundred and sixty-seven cases of ringworm of the scalp, fifty-two cases of gonorrhœal vulvo-vaginitis, four cases of purulent ophthalmia, and twenty-one cases of catarrhal conjunctivitis.

Drugs may be Sold in Pharmacies Only.—Police Superintendent McKelvey, of Brooklyn, has issued an order calling upon the members of the force to enforce the law prohibiting the sale of drugs or medicines in any store other than a pharmacy. Acting Captain Knipe, of the Twenty-sixth precinct, which covers the territory formerly known as Flatlands, has reported the names of a dozen grocers in his district who sell drugs. These persons will be prosecuted by the Kings County Pharmaceutical Association.

Medical Expert Testimony.—"The special committee appointed at the last meeting of the Medical Society of the State of New York to report upon the most feasible plan by which the present methods of introducing medical expert testimony can be improved respectfully submit the following report:

"Your committee, recognizing the difficulties which lay in the way of formulating any plan within the constitution of the State, have corresponded quite extensively with qualified members of both the legal and medical professions, and believe that in submitting the following preamble and resolution they present a consensus of such opinions held with reference to this subject, which, under present constitutional restrictions, affords the best method of obtaining medical expert testimony.

"*Whereas*, The present method of obtaining medical expert testimony tends to lessen the value of such testimony and to bring the medical profession into disrepute; therefore be it

"*Resolved*, That the Medical Society of the State of New York would recommend the enactment of a law by the legislature providing for the appointment

of experts by the courts, and that only physicians of repute in the particular branch of medical science to which the question calling for expert opinion relates shall be appointed; that the function of the experts so appointed shall be advisory, and the number thus appointed shall be such as to adequately represent the court and both sides of the question at issue, as in the judgment of the court shall seem necessary; that the experts so appointed shall have full and free access to all the evidence in the case, as well as access to the plaintiff or defendant in person, as the case may be, if the issue involves his mental or physical state; that the experts shall submit to the court for transmission to the jury a report in writing, setting forth their conclusion, and the facts in evidence upon which such conclusion is based; that the cross-examination of such experts shall be limited to the facts and opinions embraced in their testimony as embodied in their report, and that their compensation shall be fixed by the court at a rate that is reasonable for professional services of such a nature.

"Most respectfully submitted: J. B. Ransom, M.D.; Carlos F. MacDonald, M.D.; H. E. Allison, M.D.; S. B. Ward, M.D.; E. D. Fisher, M.D., *Committee*."

Dr. Daniel Lewis has resigned the editorship of the *Medical Review*.

A New City Laboratory has been established in Boise, Idaho, Surgeon Wood, U. S. A., of the Boise barracks, being in charge. The building is the joint donation of the city and some of the earnest bacteriologists of the place.

Carrying Tuberculous Infection too Far.—Fredrick Weber was struck by a Third Avenue cable car and his knee was hurt. Eight months afterward he died of consumption. His widow Barbara sued the railroad company and in the Supreme Court, before Justice Freedman, a jury gave her \$6,500 damages. It was testified by experts for the plaintiff that the knee became tuberculous in condition shortly after the accident and offered a fertile soil for the bacilli which entered his system and caused death. It was therefore maintained for the plaintiff that the accident was the cause of death. Dr. Fowler, for the defence, testified very properly that there could be no such connection between the injured knee and the ultimate cause of death.

The Scientific Education on the Temperance Question in Public Schools is not popular in Brooklyn, the comptroller of that city having refused to supply the twenty thousand dollars for the purchase of books on that subject. The objection is perfectly reasonable.

Dr. Joseph C. De Vries has resigned as resident house physician of the Loomis Hospital, preparatory to his departure for Calcutta, India, where he goes to take a post on the *Indian Medical Record*.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending February 8, 1896. February 7th: Passed Assistant Surgeon C. H. T. Lowndes, detached from marine ren-

dezvous, San Francisco, and granted one month's leave. Assistant Surgeon C. P. Bagg, detached from the *Vermont* and ordered to the marine rendezvous, San Francisco, Cal.

A Death Certificate.—This unique specimen of a certificate of death is said by an English contemporary to have been tendered by a native apothecary at an inquest in India: "I think she died or lost her life for want of food or on account of starvation, and perhaps for other things of her comfortables, and most probably she died by drowning."

The Seventeenth Balneological Congress will be held in Berlin, March 5 to 10, 1896, under the presidency of Dr. Liebreich. The secretary of the congress is Dr. Brock, Melchiorstrasse 18, Berlin, to whom all communications should be addressed.

An Anti-Cancer League.—Dr. Duplay, of Paris, proposes to organize an association for the study of the pathogenesis and therapy of cancer. He is about to establish a quarterly journal entitled *Revue des Maladies Cancéreuses*, under the editorial charge of Dr. Ozerone, which will contain original articles as well as a general review of the contemporaneous literature of cancer.

Registration of Phthisis.—An ordinance was proposed recently in one of the California health resorts providing for the registration of people suffering from tuberculosis, but it was defeated on the argument that it might lessen the reputation of California as the home of consumptives.

Total Abstinence and Longevity.—Sir George Humphry has collected information regarding 45 centenarians, of whom only 12 were total abstainers, while 30 were moderate drinkers, and 3 were heavy drinkers. Of 689 persons between eighty and one hundred years of age, as given in Sir George Humphry's tables, only a fraction over twelve per cent. were abstainers, while nearly nine per cent. were heavy drinkers.

An Unusual Form of Adulteration.—An analysis recently made of drugs sold by the pharmacists of Birmingham, England, showed that they were giving customers too much for their money, and the druggists have therefore been fined under a provision of the Adulteration Act which forbids the preparation and sale of articles of greater strength than the standard of the British Pharmacopœia. In some cases there was forty per cent. more iodine, etc., in their tinctures than there should have been.

Mr. John Chippendale, probably the oldest of English surgeons, died in London recently in his ninety-first year. He was educated at University College, London, and at Paris, and was the author of several medical works.

Foreign Medical Students in Paris.—Foreigners who are not bachelors of arts or of science or who have not obtained their degree from some approved college are to be excluded from the Paris medical schools, as the laboratories are overcrowded, and even enough subjects for dissection cannot be obtained.

Tuberculosis from Meat.—The recent death of Dr. William McLaughlin, chief United States inspector of cattle for New Jersey, is said to have been caused by tuberculosis contracted three months ago by biting into the raw flesh of a cow which he was examining for that disease.

Increase in Diphtheria Mortality.—According to *La Médecine Moderne* of January 15, 1896, the mortality from diphtheria in Paris, which for eighteen months has kept below the figure of ten per week, suddenly went up to twenty-three and seventeen respectively for the first two weeks of the year.

The frequency of the disease, however, has not increased, but, on the contrary, in the second week of January there were but ninety-four cases reported, as against one hundred and twenty-six in the preceding week.

This naturally brings up the question again: Have we been passing through a period of mild diphtheria and will the antitoxin serum prove less efficacious when the virulence of an epidemic is pronounced?

Manhattan Hospital Managers.—Governor Morton has appointed the following persons managers of the Manhattan Hospital for the Insane: Henry E. Howland, for the term of seven years; George E. Dodge, for the term of six years; Eleanor Kinnicutt, for the term of five years; John McAnerney, for the term of four years; Isaac N. Seligman, for the term of three years; Alice Pine, for the term of two years, and George S. Bowdoin, for the term of one year.

Body-Snatching in Ohio.—The janitor of the medical department of Worcester University was recently arrested on a charge of body-snatching. The authorities discovered a stolen body in the dissecting-room of the school. The newspapers announced that the school had compromised in a civil suit by the payment of \$1200, but the *Cleveland Journal of Medicine* states that this is not the case. "This incident," it adds, "is an illustration of the faulty medical laws of the State of Ohio," but we should infer that there was a screw loose somewhere else also.

The Chicago Clinical Review states that there are in the Illinois State Penitentiary seventeen convicts who are in an isolation ward and condemned to death. These convicts are all in different stages of pulmonary consumption, and are all, it adds, "incurable cases." The *Review* claims that these sick men ought not to be killed by the State.

Medical Society of the County of Erie.—The diamond anniversary (seventy-fifth) of this society was held on January 14, 1896. A historical sketch of the society was given by Dr. Franklin C. Gram, secretary. Dr. Wyckoff gave an account of the early days of the medical department of the University of Buffalo, and Dr. Cronyn told the story of the founding of the medical department of the Niagara University. A collection of photographs and biographies of the members was secured by the secretary. The Erie County Medical Society deserves to have its diamond anniversary, and deserves all the kind words said of it by

its members and friends. It has, as the *Buffalo Medical Journal* states, been one of the most active of the medical organizations of the State, and has always been liberal and progressive, yet has always aimed to serve the best interests and secure the highest standard of the profession. We are glad to learn that the anniversary occasion was made an opportunity for starting a fund to purchase a home for the society.

Dr. A. F. A. King has resigned from the staff of the Columbia Hospital in Washington because he would not countenance the unjust treatment of a member of the staff by a lay member of the board of directors. Dr. King's course, says the correspondent of the *Journal of the American Medical Association*, is cordially appreciated by the members of the medical profession in Washington.

The Boom in Medical Photography, which has been so luxuriantly in evidence, may receive a little shock by reason of the experience of a St. Louis surgeon, who has been sued for \$15,000 damages. The suit was brought by one of his patients, of whom he published a portrait in connection with a report of his case. The patient had given the physician the privilege of taking his photograph for a personal use, but not for publication.

Surgeon-General George M. Sternberg has opposed a bill introduced into the United States Senate having for its ostensible object the prevention of cruelty to animals, but, in reality, aimed at the prevention of vivisection. Dr. Sternberg says: "So far as observation goes, I do not think there is any necessity for legislation upon this subject. In my opinion, it is a mistake to suppose that those engaged in scientific investigation or in teaching physiology are any less humane than the members of the Washington Humane Society, and the passage of an act to place them under the supervision of inspectors, appointed by this society, would be an unmerited reflection upon them."—*Journal of the American Medical Association*.

An Analgesic and Antiseptic Dressing.—M. Delpech, of Paris, with the aid of M. Petit, has obtained an antiseptic and analgesic dressing, which he calls *la ouate picrique*. Picric acid was formerly used in the Spanish and English colonies as a febrifuge. Quite recently Dr. Thiéry, *chef de clinique* of the Paris Medical Faculty, published the results of his treatment of burns with picric acid, and he noted the antiseptic and analgesic action of the acid. Dr. Delpech's *ouate picrique* is prepared as follows: Purified cotton wool is steeped in a saturated solution of picric acid; the cotton wool is then dried in a disinfecting stove; square sections of this cotton wool, steeped in water, even in cold water, immediately relieves, and in a short time entirely abolishes, pain. Repeated applications of this wool, moistened, cure burns.

Dr. John B. Huber, deputy coroner, has resigned in consequence of what he considered to be derogatory remarks concerning his duties, which were made by Coroner Hoeber, his chief. Dr. Otto H. Schultz has been appointed to fill the vacancy thus created.

The Culture Tube in Diagnosis of Diphtheria.—We notice that some of our contemporaries are speaking contemptuously of the culture tube as a method of diagnosis in diphtheria, and some of the more foolish are intimating that we will soon do away with microscopes and go back to the good old style. It is true that some modifications have been made in the method by which the bacteriological diagnosis of diphtheria is made, but the value of the method is none the less great. It is now, we believe, conceded that if the cultures obtained from the throats which are supposed to have diphtheria contain no bacillus either identical with or resembling that of the Klebs-Loeffler bacillus, the case is not one of diphtheria. If, however, these organisms are found, it is not possible to make a diagnosis at once of diphtheria, without inoculations, for there is a non-virulent bacillus which in all respects resembles morphologically the true bacillus. If, however, in connection with this bacillus there are clinical symptoms of diphtheria, then the diagnosis is practically certain. Thus, the bacteriological methods have both a positive and a negative value that is extremely great.

University of the State of New York Medical Examinations.—Examinations for license to practise medicine in the State of New York will be held as follows: *Dates.*—1896: April 7-10, May 19-22, June 16-19. *Places.*—New York, Albany, Syracuse, Buffalo. Each candidate is notified as to exact place. *Daily Programme.*—Tuesday, morning, 9:15-12:15, anatomy; afternoon, 1:15-4:15, physiology and hygiene. Wednesday, morning, 9:15-12:15, chemistry; afternoon, 1:15-4:15, surgery. Thursday, morning, 9:15-12:15, obstetrics; afternoon, 1:15-4:15, pathology and diagnosis. Friday, morning, 9:15-12:15, therapeutics.

Sancta Simplicitas.—Doctors have many curious experiences, but the following production, which the London *Lancet* has received from a medical man to whom it was sent by a child, and which is printed as it was written, omitting only the name and address, would be hard to beat:

"DEAR DR. —: I would be very pleased if you would let me have a Baby for one guinea. We want it on the 4th of Febry for Mother's birthday. We would like it fat and Bonny, with blue eyes and fair hair. We Children are going to give it to her ourselves please answer at once. Yours sincerely,

"ARCHIE —."

"P.S. Which would be the cheaper a Boy or a Girl?"

The "P.S." especially is delightful, and shows how wonderful the ramifications of the commercial spirit are among us. —*Westminster Gazette*.

The Eye Troubles of Bicyclists.—Dr. DuBoys describes a visual disturbance in a professional bicycle rider which he considers due to bicycle riding. His patient, a man of twenty-three, was seized with his trouble during a twenty-four hours' race in very cold weather. About the eighteenth hour he noticed that his vision was very much impaired. A diffusion of

both corneæ was found without superficial lesion. Under the influence of warmth and rest the vision began to improve, and the corneæ regained their normal appearance.

Dr. Calavelier reports another case of eye trouble occurring in a bicycler who had ridden a race of twelve kilometres at a very rapid pace. The patient was seized with severe vertigo, ending in a sudden diminution of vision of the left eye. Examination showed traces of retinal hemorrhages.

"My Hospitals."—Paul Verlaine, the French poet, who died recently, was a dissipated and diseased character, who had to enter the public hospitals frequently to get over the results of his debaucheries. He wrote a book describing some of his experiences, entitled "My Hospitals."

A Quack who was trying to practise in England was recently arrested and fined. He claimed to have a degree of M.D. from the University of Philadelphia, but it was shown that the so-called university had its charter revoked in 1879.

The Medical Department of Vanderbilt University was reorganized a year ago. A new faculty was elected, and a graded course of three years was adopted. The school has lately moved into a new building, erected at a cost of \$70,000.

The Imperial University of Japan has 1,468 students, among whom are 175 in the college of medicine. The university includes colleges of law, literature, science, etc., but no theological school.

An Anatomical Peculiarity of Man.—Professor Rankie, at a recent meeting of the German Anthropological Society, called attention to the relative weight of the brain and spinal cord of man, and said that this ratio was so much greater in man than in the lower animals that it constituted a characteristic anatomical difference. The weight of the brain is about fourteen hundred grams, and that of the spinal cord thirty-three grams.

Three Kansas City Medical Colleges Outlawed.—Three medical colleges in Kansas City have refused to comply with the requirements of the Missouri State Board of Health, and have consequently been stricken from the list of colleges in good standing; which implies that their diplomas will not be recognized by the State Board of Health and that their students will be refused licenses to practise medicine in the State of Missouri.—*Medical Review*.

The Medical Library of Paris.—The French medical student of the present time is easily roused to wrath when suffering from a real or an imaginary injustice, but in some matters he is a long-suffering creature. The bad management of the library of the medical faculty is quoted as a proof of his meekness and endurance. During the year which is now passing away 159,180 students have consulted 270,000 volumes in the said library, these statistics giving a flattering idea of the library which is not supported by fact. The library is so over-weighted by debt that not

only new books are not bought but sixty subscriptions to publications have been discontinued. Five thousand volumes and pamphlets have been bequeathed to the library by deceased medical men. Among these thousands of volumes there were one hundred new works. Books that the library does not possess are constantly and repeatedly asked for. The medical press, with justice, considers this state of things to be hard on the medical students, who pay something toward the expenses of the library. The position of the library is a difficult one. The allowance for the new spacious library and reading-room is the same as that granted to the old one, which was much smaller and therefore comparatively inexpensive. The staff is larger and binding is a costly item, and for want of funds books remain ragged. More books than ever on medical and scientific subjects are produced, and yet fewer are bought by the medical faculty library.—*British Medical Journal*.

The Danger in Chlorosis, according to Dr. Lee Dickinson, is that in some cases there is a spontaneous thrombosis of the cerebral veins and sinuses. A series of cases illustrating this is reported.

Public Health is the title of a new quarterly journal of sanitation published by Dr. W. B. Atkinson, of Philadelphia, as the organ of the associated health authorities of Pennsylvania, the State board of health, and the State quarantine board.

The Hospital of the University of Pennsylvania was one of the beneficiaries of the very successful German-American charity, held on January 28th, Dr. Pepper, of the university, acting as master of ceremonies.

The Medico-Legal Society of Philadelphia, one of the oldest of the chartered medical bodies of that city, held its annual meeting and dinner on January 28th. The following were elected officers for the ensuing year: *President*, Dr. A. B. Hirsh; *Vice-Presidents*, Drs. W. H. Ziegler and J. B. Dripp; *Treasurer*, Dr. G. M. D. Peltz; *Secretary*, Dr. George Y. Pascoe, Jr.; *Librarian*, Dr. J. D. Nash; *Censors*, Drs. E. B. Wheeler, Thomas J. Beatty, and J. W. Mearns.

The Philadelphia Medical Club, an organization devoted to social purposes and meeting about four times during the year, held its annual meeting and banquet on January 29th and elected officers as follows: *President*, Dr. Hobart A. Hare; *First Vice-President*, Dr. Henry Beates, Jr.; *Second Vice-President*, Dr. A. K. Minich; *Secretary*, Dr. Lemuel J. Deal; *Treasurer*, Dr. Wilson Buckley; *Executive Committee*, Drs. James Van Buskirk, E. E. Montgomery, L. W. Fox, J. H. W. Chestnut, and S. D. Risley. Dr. Charles K. Mills was elected a governor for a period of five years.

Lord Wolseley and the Doctors.—The English papers state that at one of the late parades in Dublin, Field-Marshal Lord Wolseley, observing that the men of the medical staff corps attending the parade saluted on his arrival on the ground by "carrying swords," immediately directed Major-General Montmorency to

bid the medical officer commanding to issue the order "return swords," and that when giving General Montmorency these instructions Lord Wolseley added that "these men have no right to draw their swords; they are not soldiers, but civil attendants on the sick."

A Colored Boy died at Howard Hospital, on January 30th, while being anesthetized with ether in preparation for a surgical operation. Post-mortem examination disclosed the existence of miliary tuberculosis of the lungs. Not more than two drachms of the anæsthetic had been used.

Medico-Climatology.—The World's Congress of Medico-Climatology will be held in San Antonio, Tex., February 20 to 22, 1896. All communications relating to the meeting may be addressed to Dr. W. S. Rowley, San Antonio, Tex.

Yellow Fever is reported in the daily papers to be prevailing to an unusual extent, in spite of the winter season, in many of the towns of Cuba, especially on the southern coast.

Fifth District Branch.—The twelfth annual meeting of the Fifth District Branch of the New York State Medical Association will be held in Brooklyn, on Tuesday, May 26, 1896.

The American Microscopical Society will hold its nineteenth annual meeting in the new Carnegie Library Building, Pittsburg, Pa., Tuesday, Wednesday, Thursday, and Friday, August 18, 19, 20, and 21, 1896.

Meeting of Cumberland County (N. J.) Medical Society.—A meeting of the Cumberland County Medical Society was held, January 14th, at the Weatherby House, Millville, Vice-President Dr. Oliver presiding. A paper on "Drug Administration" was read by Dr. Jerome Massenger, of Millville. Dr. A. R. Judson, of Newport, gave an interesting talk on "Medicine as I Found It in Colorado," and Dr. Sullivan, of Shiloh, made a favorable report of the antitoxin treatment in diphtheria, which was based upon recent experiments in conjunction with treatment by the usual methods.

Serum Injections in Meningitis.—In the case of a seven-year-old boy in whom meningitis had been induced by an injection of pneumococci, Righi (*Gazz. degli Osped.*, October 24, 1895) injected blood serum obtained from the patient's sister, who was convalescing from meningitis. After the injection of five cubic centigrams the symptoms of danger disappeared, the fever was reduced, and the patient rapidly recovered health.

St. Louis Doctors.—St. Louis doctors, we are told by the *Evening Post*, not only differ, but quarrel over their differences. The disturbance is due to the very sensible efforts of the State Board of Health to increase the standard of education of physicians by requiring a higher degree of general education on the part of applicants for admission to the medical colleges. Unfortunately for the cause, the chairman of the board is a member of the faculty of one of the medical schools, and this makes the opportunity for

the officers of schools which are hit hardest by the new rule to assert that its purpose was to advance the interests of one college at the expense of the others. The fight waxes over this charge, but meantime the rule is being enforced, with the result that the uneducated are being weeded out, 101 of 165 in the junior class of one college being barred. The chairman of the Health Board makes public the charge that some of the medical colleges are run purely for the money there is in them, without any regard for the ultimate benefit or injury to the public.

The Larrey Prize of the Academie des Sciences.

—The late Baron Larrey, son of Napoleon's surgeon, has left a bequest to the Paris Academy of Sciences for an annual prize of 1,000 francs for the best treatise by an army doctor on any question of medicine, surgery, or sanitation.

Comparative Mortality of New York and Philadelphia.—A comparative study of the morbidity and mortality in the cities of New York and Philadelphia from what are designated "contagious diseases" discloses some interesting facts and affords food for reflection. Thus, for the weeks ending January 18th and 25, the figures, as published, may be tabulated as follows:

	PHILADELPHIA.				NEW YORK.			
	January 18.		January 25.		January 18.		January 25.	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
Diphtheria	61	22	55	18	332	40	279	48
Typhoid fever . .	46	8	35	7	3	5	12	5
Scarlet fever . .	25	1	34	2	214	21	195	23
Measles	..	8	..	9	330	22	430	22
Tuberculosis . .	..	58	..	47	128	119	160	125
Cerebro-spinal meningitis . .	..	1	..	..	1	3	3	3
Small-pox	..	..	..	..	1	0	0	0

If these figures show anything, they clearly demonstrate the disproportionately large number of cases of typhoid fever in Philadelphia. The discrepancy may be attributed to the differences in the character of the water supply of the two cities. New York, on the other hand, has a much larger number of cases of scarlet fever and diphtheria, and apparently also of measles and tuberculosis, but the mortality from diphtheria is distinctly the less. This condition is due in part to the fact that in New York membranous croup is included with diphtheria, and probably also in part to the more general use of the antitoxin in the same city. The large prevalence of scarlet fever, measles, and diphtheria in New York is no doubt to be attributed to the greater crowding and density of population.

The annual statement of the chief medical inspector of the Board of Health, just issued, shows that during the year 1895 there were reported 3,351 cases of diphtheria, 502 cases of membranous croup, 1,195 cases of scarlet fever, 2,748 cases of typhoid fever, 309 cases of small-pox, 12 cases of cerebro-spinal meningitis, and 1 case of typhus fever. Disinfection and fumigation of houses was practised 5,205 times. Pulmonary tuberculosis was reported as the cause of death in 2,449 cases.

There was a forcible demonstration of the infective-

ness of pneumonia in the death from this disease of four persons in one family within a period of five days.

Obituary Notes.—DR. ISAAC H. BARBER, one of the best-known physicians in Brooklyn, died February 5th, after a long illness. Dr. Barber was a native of Montgomery County, N. Y., where he was born in 1829. He was graduated from the New York College of Physicians and Surgeons in 1851, and soon afterward was employed on the Vanderbilt lines of steamers running to the Chagres River. He later became harbor surgeon at Chagres River. Nearly forty years ago he settled in Brooklyn. A widow and one son, Dr. Calvin F. Barber, of South Oxford Street, Brooklyn, survive.

DR. MARCUS L. TAYLOR, aged 45 years, of Booneville, Miss., who for nineteen years was attached to the medical department of the United States army, died in Philadelphia January 25th.

DR. ALFRED D. KENNEDY.—As the result either of an explosion or of an accident, it is not known which, Dr. Alfred D. Kennedy, of Philadelphia, a noted physician and scientist, was burned to death in his laboratory on January 30th. He was a volunteer surgeon during the war of the Rebellion and was an expert in botany, geology, chemistry, and civil and mining engineering. He was born in Philadelphia in 1818, and was graduated from the University of Pennsylvania in the year 1838. He was at different times assistant professor of chemistry, lecturer on chemical physics, and on general and medical botany and medical jurisprudence and toxicology in the Pennsylvania College, and lecturer on medical chemistry in the Philadelphia School of Medicine. In 1842 he established the Philadelphia School of Chemistry, and remained at its head until 1853, when it became the Polytechnic College of the State of Pennsylvania. He also occupied many other prominent positions.

DR. RICHARD MANNING HODGES, visiting surgeon to the Massachusetts General Hospital, and a professor of surgery at Harvard, died February 10th, in Boston. Death was due to heart failure. He was seventy years of age. He was an overseer of Harvard College for two terms, a fellow of the American Academy of Arts and Sciences, and a member of various medical and social organizations of Boston.

DR. H. ERNEST GOODMAN, a well-known and popular surgeon, died suddenly on January 7th, while riding in a suburban train to visit a patient. He was born in 1836, and graduated from the University of Pennsylvania in 1859. On the breaking out of the war he entered the army and made an enviable record during his four years of service. He was physician of the port from 1866 to 1872, and one of the originators of the Orthopaedic Hospital (to which institution he was surgeon at the time of his death), and of the Pennsylvania State Hospital for Women (to which he was consulting surgeon). He was at one time professor of surgery in the Medico-Chirurgical College. He was also surgeon to Wills' Eye Hospital.

DR. W. W. JAGGARD, a well-known physician of Chicago, died in that city of appendicitis on January 30th.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

LONDON UNIVERSITY—COLLEGE OF SURGEONS AND MEMBERS—HARVEIAN SOCIETY—ETHICS AND THE GYNECOLOGICAL SOCIETY—SPELLING, AMERICAN AND ENGLISH.

LOST 18, January 4, 1896.

CONVOCATION of the London University met on Tuesday, and voted for reconstruction by a large majority—466 to 240. The scheme thus supported deprives convocation of its present power of veto, so some consider it a self-denying decision. There was a fair discussion of the plans. The opposition wish to have the opinion of the members at a distance, and it is thought that the government will not proceed with the bill until this has been ascertained. But under its charter the only constitutional way for convocation to express its views is in the assembly, and other universities have had to abide by the decision of those who could manage to attend. Whether we are any nearer the settlement of this vexed question remains to be seen, but if it continue to be agitated much more, the public may come to think that the most drastic reforms should be forced through parliament. The university hardly deserves the name. It is only an examining board, and maintains its prestige by the severity of its examinations, the obstructiveness of its regulations, and its locality within the metropolis. London doubtless ought to have a great university, but can it be gained by reconstructing this?

The Society of Members of the College of Surgeons has determined to wait quietly the result of its late victory, in order to see what will be the effect on the committee of the Council. This is probably wise, for its cause has made a distinct advance. The fellows now recognize the claim of members for some representation, and the principle once admitted details are of secondary importance. The fellows should take the full plunge and allow members to vote for candidates of either grade. The position of the fellows would always secure them their full representation.

The annual meeting of the Harveian Society was held on January 16th, when the report showed a satisfactory state of the finances, with a membership numbering four hundred and eighty. Sir John Williams, the president, delivered an address, in which he reviewed the changes that have taken place during the last thirty years in the examinations in midwifery and during some forty years in obstetric practice and operations.

A pronunciamento on ethics by the Gynecological Society provokes some irreverent members to talk about Saul among the prophets. It seems the editor of *The Lancet* had inquired how many homeopaths there were in the society and suggested that it was undesirable that such should be admitted, whereupon the council framed a new by-law excluding them. This was submitted to the annual meeting, and was passed after a feeble protest and a suggestion that it should be regarded as a pious opinion rather than a law. It is not very clear why the editor of *The Lancet* should interfere in such a matter. Perhaps he only inquired of this and other societies in an access of statistical zeal, in which case the terror of the council seems excessive. Be that as it may, once started on the war-path the council was not satisfied with its new ethical by-law, but added another to this effect: "It is contrary to the ethics of the British Gynecological Society that any of its fellows should advertise their publications, or otherwise bring themselves before the notice of the public by advertising in any way through the

medium of the lay papers. The council would look with disfavor also on announcements sent round to the medical profession generally."

This curious form of a by-law might well be called a "pious opinion," but it was duly adopted by the society and will probably be just as much disregarded as more rigid laws have been. It may, however, deliver us from the inundation of papers on gynecological subjects, in which presumably the interest of many is not very intense. Of course a correspondent of such a paper as the *MEDICAL RECORD* must, like an editor, keep his eyes and ears open on all departments, but there are a good many practitioners who rejoice to be able to close them to gynecology.

Writing this word reminds me that the question of discarding useless diphthongs has again come up. Of course you Americans have settled it long ago. Some are inclined to accept your decision, but the majority profess to be shocked with such barbarism as not following the Greek, and that, too, after the outcry that modern language should replace the ancient in our academies and the fact that the London University has fairly strangled Greek for its graduates.

Spelling-reform of this kind is more likely to be accepted by medical than literary publications. In fact some proposals have originated with us. Dr. George Harley some years ago made an effort to dispense with useless double consonants, but he did not get much support. Shorthand is a terrible enemy to our spelling, and now Dr. Gowers, who is the leader of those promoting shorthand for medical students, has taken up the subject of the troublesome diphthongs, avowedly on account of the United States practice. He has appealed to Professor Skeat, whose authority none will question and who clearly inclines to American usage, for though he remarks that in cases of doubt every man must "make his own laws," which I suppose means follow his own taste, yet he observes that in his new English dictionary while *anamia* is the adopted spelling, *anemia* occurs in one of the examples. It is, he says, a question of date. The Latin *æ* became *e* in French, so words coming through French are spelled with *e*, as *primeval*, and he is trying to introduce *medieval* to pair with it. There is now in Cambridge a "medieval" tripes. Professor Skeat says forcibly: "There is no *æ* or *æ* in English; it is always pronounced as *e* and might just as well be so written. The use of writing is to represent the sound of the words, not to be everlastingly harping upon the Greek and Latin forms. But few people can see this; and when a thing is wrong they stick to it all the same."

After this, perhaps, literary as well as medical men may modify their opposition to change. If not they should write *cæ*lestial, just as medical sticklers for etymology should write *aneurysm*, and so on. Really, spelling is so confused I think the professor is right, "every one will make his own laws," and so we shall, perhaps, return to the simple method of Chaucer. Personally, however, I prefer the more uniform United States usage.

"Cold in the Head" in Infants.—J. Bermann, of Washington, thinks cold in the head in infants very frequently leads to serious trouble later in life and ought not to be neglected, as it too often is, but should be treated with a two-per-cent. solution of nitrate of silver applied to the throat with a soft brush. Care should be taken not to use the fluid so freely that it will drop into the larynx. If the child makes any noise in breathing through the nose the next day apply the nitrate of silver again. By treating an acute rhinitis in an infant, catarrh, deflections of the septum, or affections of the ear may often be avoided.—*Archives of Pediatrics*.

OUR PARIS LETTER.

(From our Special Correspondent.)

FRENCH QUARANTINE REGULATIONS—QUARANTINE ABOLISHED—DISINFECTION BY HOT AIR—LETTERS AND NEWSPAPERS EXEMPT—RAGS AND HIDES TO BE THOROUGHLY DISINFECTED BEFORE SHIPMENT TO THE UNITED STATES.

PARIS, January 25, 1896.

QUARANTINE regulations, as well as those relating to public health and hygiene in general, have taken a fresh impetus in several of the European countries, more especially those possessing seaport towns. It was Italy quite recently and now it is France. Doubtless the new regulations issued by the American treasury department regarding the disinfection of rags to be shipped to the United States for the manufacture of paper have done great good in causing foreign governments to take active measures to prevent the spread of contagious diseases either on the seaboard or through the interior. Only two weeks ago the Italian government put into force its new sanitary police regulations. About the same time orders were received in Paris from the United States treasury department that only hides cured by salt or arsenic could be shipped to the United States from France without being previously disinfected. In every other case the bundles of hides must be unbound and each separate hide soaked for half an hour in a solution of corrosive sublimate, one to one thousand of water. Of the various methods for the disinfection of rags that usually employed here (also in accordance with the United States quarantine regulations) is to spread them in layers of not more than six inches in depth, on racks, and thus expose them for six hours at least to the fumes of block sulphur burned in a brazier in a tightly closed room. The proportion is three pounds of sulphur to one thousand cubic feet of space.

The French government in its turn has just issued a fresh decree bearing upon the disinfection of passengers and mails, the prevention of epidemics, and the spread of contagious or infectious diseases in general. This decree is a decided improvement on that hitherto in force, in that it gives greater guarantees for protection of the public health. What is most remarkable about it is that it suppresses quarantines altogether and replaces them by precise sanitary information; by prophylactic measures taken either at the departure of or on board the ship under the direction and control of a physician, especially appointed for that purpose, and by a medical supervision whenever necessary of passengers at liberty for a length of time corresponding to the period of incubation of the disease in question. Special advantages, such as a notable reduction of taxes, are accorded ships having on board a hot-air disinfecting-stove and a sanitary physician who can certify on arrival that all the prescribed measures of disinfection, hygiene, and cleanliness have been rigorously carried out during the voyage.

Cholera, yellow fever, and the plague are the only pestilential exotic diseases that determine the application of permanent sanitary measures; other serious contagious diseases, more especially typhus and small-pox, may demand special sanitary and prophylactic precautions. It is of course understood that precautionary measures can always be taken against any ship the hygienic conditions of which are judged dangerous by the sanitary authorities. Each and every ship arriving at a French port is to be subjected to a different régime, according as said ship may be free from contagious or epidemic diseases, suspected, or actually infected. In the first two cases the passengers and crew are to undergo a sanitary supervision and the

ship is to be disinfected; in the last case those affected with either of the diseases to which the regulations are applicable are at once disembarked and isolated until cured; the others are to be submitted to observation in a hospital, the length of the observation varying according to the disease and the date of the last case; the ship is to be isolated and disinfected.

It is strange, however, in a law that is evidently intended to be so searching that disinfection is not applied to mail matter as well. Mails can be circulated, received, and delivered without any restriction or disinfection whatever. This includes letters and correspondence, cards, printed circulars, books, newspapers, magazines, business papers, and official documents. The only exception made is against postal packages.

The physicians serving on board of French ships must be chosen from a list drawn up by the minister of the interior after an examination passed before a special jury. Every French steamship carrying the mails or at the least one hundred passengers and making a voyage the duration of which including landings passes forty-eight hours, must have on board a marine physician who also is a sanitary inspector. These regulations are now in force both in France and Italy, being based upon the resolutions drawn up by the congress at Dresden. It will be seen that great progress has been made in the last few years in sanitary and quarantine matters and that quarantine itself is gradually being abolished as inefficacious; that and sanitary cordons, however closely kept, never have stopped and never can stop the passage of microbes. The only true safeguard is their absolute destruction by heat and disinfection. No ship need ever be detained more than forty-eight hours at longest, and that long only in very exceptional cases. The system of disinfection by the hot-air stove is the best known to science and that now almost exclusively used in France, whether in the inland hospitals, on the seaboard, or in the ships themselves.

MEDICAL EXPERT TESTIMONY AND AN "EXPERT COMMISSION."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your editorial on the "Advocacy of Expert Commissions," which appeared in the issue of the MEDICAL RECORD of January 25th, after referring to the discredit which has been thrown upon medical expert testimony in the past few years, you conclude with the opinion that "the only reasonable way to overcome such difficulties would be to create a commission of experts which should be entirely independent and absolutely impartial in its expression of scientific opinion in a given case." If this opinion could be put into execution the question would be solved in a very satisfactory manner, but unfortunately the enactment of a law authorizing such a commission would probably prove to be as lamentable a failure as the present method is. The fault of the present system lies at the door of the lawyers, and not with the experts. In all cases of any prominence both sides to the controversy secure the best experts available. They are usually men of the highest attainments in different branches of medicine; men who have stood before their brethren and the community at large for years without a smirch upon their professional ability or private character. Is it reasonable to believe men of this stamp would testify to what they know or think to be false? The opinion is also held by many that the expert's view of the case is frequently influenced by the pecuniary consideration he receives. Is this a reasonable hypothesis? Most of

the experts are men whose abilities have not only placed them beyond want, but, from a physician's point of view at least, they are in more than comfortable circumstances, and certainly not in a position to be tempted by the very moderate fee received in the majority of cases. It is the popular idea that experts receive enormous sums for their testimony. This may have been true in cases in which large sums of money were in dispute. But in the majority of cases the fee is a very moderate one and in many criminal cases the expert receives no fee at all, either being actuated by the desire of acquiring experience or else in response to an appeal for help giving his services because he does not desire to see an injustice perpetrated. In any event, if expert testimony could be purchased, such transactions could not possibly be kept secret for any length of time, and no attorney could afford to prejudice his case by allowing a purchased witness to take the stand. The fault does not lie with the experts but with the lawyers. In many instances the expert merely gives his opinion, based upon a series of alleged facts assumed in a hypothetical question. The expert upon the opposing side does the same. Each gives an honest opinion, based upon logical reasoning, and yet the two opinions are absolutely antagonistic.

The reason for this is obvious. The opposing experts are not asked the same question. The hypothetical questions put to each contain, as a rule, diametrically opposite suppositions of fact and therefore, the experts' opinions must differ. If the experts on both sides were asked the same hypothetical question there would seldom be any material differences in the resulting opinions. But this is a course which the opposing counsellors cannot follow. They attempt to prove opposite conditions of fact, and, therefore, present skillfully prepared questions to their experts, the answers to which are calculated to support their side of the controversy.

The answer to a hypothetical question is merely an opinion based on assumed facts, and should be carefully differentiated by the jury from an expert's opinion based upon facts the result of personal observation and investigation. It is for the attorneys to prove to the jury that the facts assumed are true. This being accomplished, the expert's opinion based upon those facts then becomes important, and then only. In many cases, such as contests over wills and again where the plea of transitory insanity is urged, and in other cases also, the expert's testimony is entirely confined to answering hypothetical questions and in giving opinions on assumed facts which are entirely without his knowledge. In other cases opinions based upon personal investigations are submitted by the experts, and here again the opposing experts may differ widely.

A careful alienist rarely bases his opinion of an individual's mental condition upon the exhibition of the objective symptoms alone. The subjective symptoms and, what is often of far greater importance, the family history, the peculiarities of character and disposition shown by the alleged lunatic, the history of strange and incomprehensible actions, and many other factors of a similar nature, are all taken into consideration and given their proper value. The major part of this kind of information is obtained either through the counsel or through the family and friends of the accused. Do the experts on both sides have equal facilities for making thorough examinations of alleged lunatics? Do they go into court prepared to give opinions based on facts and information imparted impartially to both? The answer to both of these questions is emphatically, No, and the answer can never be anything else so long as attorneys have the power and exercise it of interfering with medical examinations.

The attorney for the accused may afford the expert he engages every facility for making a thorough medical examination, and supplies him with information gleaned from the examination of prospective witnesses which has a tendency to prove the existence of those changes in character, temperament, and disposition which are so often the precursory symptoms of mental disease. The expert thus readily obtains the history of insane acts and speeches, if there have been any, and the history of all other facts tending to demonstrate mental disease. But how does the attorney act with the medical expert called by his opponent? Does he assist him as he did his own expert? Of course not. He is often present when the examination is made, and either instructs his client not to answer certain questions or else not to answer at all. If the expert attempts to obtain information from the friends or family of the accused, he is either rebuffed or misled. In fact he receives little knowledge except that which he obtains from a personal inspection of the accused. This meagre information is supplemented by a recital of assumed facts by the attorney retaining him, consisting of statements which, it is needless to say, are diametrically opposite to those supplied to the expert on the other side.

Is it at all remarkable that, under such circumstances conflicting opinions result, or at all strange that expert medical testimony should be regarded with suspicion and distrust? I agree with the writer of your editorial that something should be done to correct this evil, which is surely casting undeserved discredit upon an important branch of medicine, but I do not believe the course suggested, that is, the appointment by the court of a commission of experts to inquire into and report upon the mental condition of the alleged lunatics, will at all result in a satisfactory solution of the question. In the first place, what guarantee is there that the court will appoint experts who are well-trained alienists? This is not a trivial question, but is one which is suggested by the proceedings in one of our courts of record a few months ago. In that case a wretched paranoiac was defended by an alienist of acknowledged repute, whose testimony was given without reward or expectation of reward. Opposed to him were two physicians, virtually appointed by the court. They were reputable physicians and men of high character, but utterly inexperienced as alienists. They could see no evidences of insanity and so testified, and the lunatic was condemned to death. They were evidently honest in their convictions but were clearly incompetent to act as experts.

But let us suppose for the sake of argument that a commission of competent experts was appointed. Their report would be in the nature of evidence for the jury to consider. But neither the creation of this commission nor the passage of any law would deprive the accused of his constitutional right of producing witnesses whose testimony would be beneficial to his cause. He could, therefore, produce all the medical expert testimony he pleased, perhaps the testimony of men of equal eminence to those composing the commission. The evidence thus obtained would also be given to the jury and the same disheartening spectacle of expert against expert would be repeated again, and thus prove to be an utter failure.

The best solution of the question to my mind is this: Let the experts from both sides have identical facilities for examining the accused without any interference in any way on the part of the attorneys. Neither expert should be allowed to make an examination of the accused or his family or his friends without the other expert being present, and the entire proceedings in every examination should be recorded by an official stenographer, such report to be placed at the disposal of the attorneys of both sides to be used

in the trial. Any information imparted to one expert relating to the mental condition of the accused should be given to the other expert also, and a full statement of this information should be incorporated into the official record. By this means all the facts of the case would be shared by both experts equally, and the official record in the hands of the attorneys would effectually check any possibility of either expert deviating from the truth or attempting to distort the facts. This is a simple method. It is fair to both sides, and will bring out the truth better than any commission could possibly do. In cases in which the expert merely gives his opinion on a hypothetical question no remedy is needed. The attorney must prove the alleged facts contained in the question before the expert's opinion is entitled to any consideration by the jury.

GRAEME M. HAMMOND, M.D.

NEW YORK, January 25, 1896.

TENDON GRAFTING—A REPLY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I wish in justice to myself to make this further reply to Dr. Milliken's letter in answer to mine in the MEDICAL RECORD for January 11th of the present year.

When unexpectedly brought to task for his extensive claims upon the subject of tendon grafting, Dr. Milliken seems ready enough to acknowledge others' endeavors in the same direction. He, however, readily convinces one that he is not yet able to appreciate the great difference between a general law and the minute methods of carrying that law into effect.

I admit that I was guilty of using catgut deep sutures instead of kangaroo tendon; I admit that I may not have used the exact number of sutures he did, and that I now forget whether the sutures were interrupted or continuous; I admit that I sewed the tendons together (or grafted them) without cutting them, while he cut two tongues and then sewed them together; I admit that I did not preserve the two tendon sheaths entirely in the first operation; I did so in a second case long before his operation; I admit, finally, that I did not have to use balsam-of-Peru to heal a pressure sore. But do these differences give Dr. Milliken the right to claim an original principle and operation?

Clearly not.

I was very glad to read the report of Dr. Milliken's case, but why did he not report it as a modified operation?

I can see no reason other than the one he suggests—that I had failed to fulfil my promise to report further upon my cases since December 11, 1892. He, therefore, guessed I had dropped out of the field and his claim would not be questioned.

I wish to say here that the reason I have not given further reports upon these cases is that unfortunately I have been laid up in bed and on crutches since April, 1893, with a chronic synovitis. When I return to practice I shall endeavor to accommodate Dr. Milliken with further reports. In the mean time I shall be pleased to read his reports.

In regard to Nicoladoni's suggestion in 1881, that was brought to my knowledge by the kindness of Dr. Royal Whitman, of New York, and was reported by me at the time the case was shown at the Academy. In that, too, if I mistake not, he cut the tendons entirely off, since he "grafted in a manner similar to grafting of trees."

Why did not Dr. Milliken mention this in his "original" article? If this suggestion of Nicoladoni's prevents my claim to originality, I cannot understand why it allows Dr. Milliken's claim to the same thing.

As far as getting rid of adhesions is concerned, Dr. Milliken employs the method with which he best suc-

ceeds, and I that with which I best succeed. But this does not allow his claim to a new operation or principle.

Finally, I think, sir, that Dr. Milliken could with equal grace claim originality of principle and operation for exsection of a tuberculous hip-joint, because in doing that operation he might have used kangaroo tendon and a fascia knife in some parts of it; or because he used one or more sutures more or less than some one else may have used.

MIDWAY, KY.

INFLUENCE OF A VEGETABLE DIET UPON LONGEVITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: With pleasure I read in your issue of January 4th an item entitled "How to be a Centenarian." I certainly agree with Sir Benjamin Ward Richardson, and I gave expression to my views on longevity in an article, "The Physiological and Pathological Influence of Vegetables upon Man," published in the MEDICAL RECORD on January 20, 1894. I there wrote: "Not only is height dependent upon a vegetable diet; also longevity and mental development are largely influenced by it. This we may infer from the fact that people in bygone years and centuries, at a time when meat was consumed much less generally and in much less quantities than now, not only were larger but also lived longer. It is self-evident that a structure constantly being kept in repair, a building whose main walls of support are constantly looked after, and any damage, slight as it be, immediately remedied, will naturally last longer. Again, it is also known that the first to suffer in another building left to itself are those parts upon which the safety of the house rests, and not the façades or any other ornamental work. Just the same is it in man. Bone is the first to show signs of weakness, when all other organs still do their work satisfactorily. This, however, is conjecture, and even if vegetables are not the only causative factor of longevity, a factor they certainly are."

Of course, the entire question of the causes of longevity necessarily cannot be deduced from actual experiments; they have to be inferred from observation and such scientifically established doctrines, a collection of which might bear upon the elucidation of the subject in question. In the question of longevity we can simply give the habits of centenarians and consider their tenacity of life in the light of our recognized physiological principles. Since the publication of my article mentioned before I have been much interested in the question of longevity, and I would mention the following abstracts confirmatory of my previously expressed views: Sir George Humphry says ("Habits and Family History of Centenarians"): "The average centenarian qualities are precisely those which might have been anticipated—a good family history; a well-made frame of average stature (5 feet 8 inches, which is rather above the average, in the male; 5 feet 3 inches in the female): . . . with little need of, and little consumption of, alcohol or animal food. . . . It is, perhaps, scarcely less important to note that our centenarians were for the most part small meat eaters." Hufeland says (translation of, London, 1797): "Is it possible to prolong life? Undoubtedly it is. . . . In the choice of food one should incline more to vegetables. . . . We find that it is not those who lived on flesh, but on vegetables, pulse, fruit, and milk who attained to the greatest age. . . . The Brahmins by their religion are confined merely to vegetables, and for the most part live to the age of one hundred."

It seems to me that I have been successful in giving scientifically the relation between cause and effect as regards longevity in my article above mentioned. I agree with Sir Benjamin Ward Richardson, and while I should advise the eating of much vegetable food in order to promote longevity, I would likewise insist upon considerable animal diet for other salutary reasons.

"THE WHITE THROAT OF THE LAKE."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the January 11, 1896, issue of your excellent journal I find a column on page 55 devoted to an article on "Septic Tonsillitis in Switzerland," by Dr. S. A. Tidey.

The statement is made that at Geneva this particular tonsillitis is termed the "white throat of the lake," or, in French, "la gorge blanche du lac."

Allow me to state, as a medical graduate of the University of Geneva and for several years assistant at the Butini Hospital for Women and Children in that city, that during the eight years I resided there I never heard of the above type of infectious throat disease.

In the last edition (1894) of their very complete "Manuel des Maladies de l'Enfance," my esteemed friends, Professor D'Espine and Dr. Picot, acknowledged authorities in the matter of infantile pathology and both of Geneva, make no mention of this form of tonsillitis.

That diphtheria is becoming more prevalent in Geneva has been asserted by Professor Revilliod, who, by reason of his enormous hospital and private practice, is most competent to make such a statement.

It would be most interesting to learn from what source our esteemed English confrère has received his information. CHARLES GREENE CUMSTON, M.D.

826 BEACON STREET, BOSTON, MASS.

BICARBONATE OF SODIUM IN THE TREATMENT OF A COMMON COLD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In an article with the above title, in the MEDICAL RECORD of January 18th, Dr. L. Duncan Bulkley claims that bicarbonate of sodium will control a cold, and he asks that a careful and fair trial be given by the profession. I want to state that I have tried the same remedy for the last six years, and have found that it would not only cure a cold but would also prevent future attacks; not that I kept my patients on bicarbonate of sodium, but I removed the cause, and that was the indigestion. I do not believe the soda cures the cold, but it cures the etiological factor, and the cold, which is a symptom of the indigestion, disappears.

I had patients that were subject to cold every two or three weeks in the winter, and I kept them free from the complaint for years by keeping their digestive apparatus in proper condition. In the majority of cases I put them on bicarbonate of sodium and hot water, but I have also found in cases where I cured the indigestion by other means that the same good result followed.

Following the theory that catarrhal inflammation of the mucous membranes is caused by indigestion, I have tried the same treatment in chronic pharyngitis with very good results.

I therefore conclude that it is not the bicarbonate of sodium especially which cures the cold, but anything that removes the indigestion.

L. W. ZWISOHN, M.D.

266 EAST 78TH STREET.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 6, 1896.

WILLIAM M. POLK, M.D., VICE-PRESIDENT, IN THE CHAIR.

Subphrenic Abscess.—DR. CARL BECK read the paper (see p. 217).

DR. R. F. WEIR opened the discussion. He had seen only five cases of subphrenic abscess, four acute, one comparatively chronic. Of the acute cases two started from an appendicitis, the pus travelling up between the liver and the diaphragm; the other two resulted from perforation of the stomach. The fifth case was reported to him as one of phlebitis: abscesses were found in the liver and one between the liver and the diaphragm. Abscess was proven in this case first by hypodermic needle, then a trocar was introduced. Inspiration made the outflow of fluid much more rapid. The reverse would probably have been true had the fluid been in the pleural cavity. If air were mixed with the fluid it would blow out a flame on inspiration following puncture. He thought this point of some value in differentiating between subphrenic abscess and collections of pus and air in the pleural cavity, especially on the left side. Subphrenic abscess probably occurred much oftener than we supposed. The cases should not be left too long in the hands of physicians, although he did not mean by this that they never effected a cure without operation.

A New Term for an Old Affection.—DR. F. G. JANEWAY said he had seen pus accumulations between the liver and the diaphragm before the condition was spoken of as subphrenic abscess. The last four cases had been operated upon, one by Dr. W. T. Bull, the abscess having originated in an appendicitis. This patient died, as did two of the others. According to his observation there was greater mobility of the diaphragm in cases of subphrenic pyopneumothorax than in cases of pure subphrenic pus accumulation. The second case had been aspirated for empyema and no pus was found; the patient was taken to the hospital, where Dr. Janeway saw him. An opening was made below the diaphragm on the left side, and pus escaped. The exact cause of the abscess was not learned. The third case was seen with Dr. Kelly; the abscess was opened, and after recurring sepsis the patient finally recovered. The abscess was on the left side, and had caused pressure on the lung and breathing of bronchial type, such as he would rather have expected to find in sacculated empyema or pyopneumothorax. The fourth case was operated upon by Dr. Flührer. The woman had recovered ten years before from supposed empyema which perforated into the lung. The same physician saw her in her last attack. Dr. Janeway thought it was a subphrenic abscess, due possibly to ulcer of the stomach, and the subsequent course of the case proved the correctness of the diagnosis, for gastric juice escaped with the contents of the abscess. The patient died of pneumonia.

Besides these cases Dr. Janeway had seen two of subphrenic abscess on the right side due to carcinoma of the pylorus with ulceration, and two of the left side from ulceration of the stomach, and a third without known cause, all without operation.

DR. PARKER SYMS had operated upon three cases of subphrenic abscess since last July, all recovering. Two gave a history of trauma; in the third the cause was not discovered. All the abscesses were intraperitoneal, and were not confined in close contact with the diaphragm. One was in a woman who had sustained a contusion of the abdomen eight weeks before

and had a small amount of pus in the urine, pointing in the first place to perinephritic abscess. Another case was that of a boy who three weeks before had been injured in the right side and a diagnosis of abscess of the liver was made. The patient was nearly moribund when operated upon in his absence by Dr. Gibbs, who found a large subphrenic abscess extending low, but recovery followed.

The Influence of Sex.—DR. S. J. MELTZER had collected 110 cases; 58 were in men, 52 in women. Five were bilateral, 4 of them in women. Of the 48 unilateral cases in women 34 were on the left side, 14 on the right, whereas in the 54 cases in men 41 were on the right side, 13 on the left. Simple gastric ulcer was one of the principal primary causes, 32 cases, 28 of which were in women, 4 in men. Duodenal ulcers were a cause in 7 cases, 2 in women, 5 in men. Of 13 cases of appendicitis 11 were in men.

The diaphragm phenomenon of Lytton was not of much value in differentiating between empyema of the chest and subphrenic abscess, being vitiated by the paresis accompanying the latter and preventing deep inspiration.

DR. BECK had no doubt that the three fatal cases related by Dr. Janeway would have recovered had he been called earlier. He believed that subphrenic abscess, like appendicitis, would be proved to be a comparatively frequent affection.

The Deformity of Hip Disease Illustrated by Automatic Models.—DR. A. B. JUDSON showed some simple automatic paper models useful in demonstrating the deformity produced by hip disease. By their aid one could readily understand why there was apparent lengthening in the presence of real shortening where ankylosis took place in abduction. Adduction also apparently increased the stature. But flexion with ankylosis reduced the height in fact and in appearance. Dr. Judson also showed a goniometer which he had found useful in determining the angle of deformity.

Electric Centrifuge for Urine.—DR. H. G. PIFARD showed an improved electric centrifuge for testing urine, milk, etc. A centrifuge shown by him two years ago had to be turned by hand and required seven minutes. The present one dispensed with the hand crank and might be termed the lazy man's centrifuge. The speed had five variations, the lowest 1,080, the highest 1,420. One would be surprised at the amount of dirt deposited from most samples of milk.

SECTION ON GENERAL SURGERY.

Stated Meeting, February 10, 1896.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Appendicitis due to Traumatism.—DR. W. B. COLEY presented a boy of sixteen who had applied at the hospital for a truss January 13th. He had no hernia, but gave a history of having been struck in the right iliac region by the handle of a push cart three days before. There was considerable pain and some vomiting the same night. On examination Dr. Coley felt a distinct tumor in the right iliac region, marked tenderness most acute over McBurney's point, and some pyrexia. At midnight the temperature rose to 104° F., and in his absence Dr. Curtis operated and found an abscess about the size of an English walnut just within the abdominal wall. The tip of the appendix was gangrenous. The wound was left open and was now closing by granulation. The case was interesting as an example of a patient with appendicitis walking about on the verge of general peritonitis and giving distinct history of trauma as a cause.

Patent Urachus.—Dr. Coley also showed a baby, aged three months, with patent urachus, through which

at the umbilicus urine constantly trickled, wetting the bandages. On pressure over the bladder the fluid came out in a stream. It was the only case seen at the hospital for five years. The opening would probably close spontaneously after a time; if it did not it would be operated upon.

THE CHAIRMAN thought it somewhat strange that we did not see more cases of appendicitis of traumatic origin, since blows in this region not infrequently caused laceration of the ileum.

DR. SAMUEL ALEXANDER had recently operated for patent urachus in a man twenty-five years of age. During all these years he had been annoyed by trickling of urine at the umbilicus, yet a simple operation gave complete relief. He dissected the mucous membrane, transfixed and ligated with catgut, refreshed the edges of the abdominal opening, closed it, and obtained primary union.

Peculiar Malformation.—THE CHAIRMAN was reminded by Dr. Coley's second case of one of peculiar malformation in an infant. This was a large umbilical hernia extending down to a tumor covered with mucous membrane. It was found to be exstrophy of the bladder, through the apex of which faeces escaped. There was a lack of union of the symphysis pubis, and absence of anus. The infant was presumably a female. As nothing could be done, it was left to its fate.

Foreign Body in the Appendix, Weight One Drachm.—DR. JAMES P. TUTTLE presented a tapering cylindrical concretion weighing three grams and a half, found in the abscess of an appendiceal case. It was probably fecal, but had not been opened. The man was aged, was in extremis, and died.

Seeds in Only One of Two Hundred Cases of Appendicitis.—DR. GALLANT had been given opportunity to examine the appendix in two hundred operative cases and had found seven strawberry seeds in one, while none of the rest contained more than a fecal concretion in the form of a foreign body.

Notes on a Series of One Hundred Consecutive Cases of Appendicitis.—DR. ROBERT T. MORRIS sent the paper, which was read by the secretary, Dr. J. B. Walker. The death rate had been two per cent., the hernia rate zero. Acute appendicitis with abscess, 34; chronic appendicitis with abscess, 4; acute appendicitis without abscess, 12; chronic appendicitis without abscess, 40. The others were cases of tuberculosis and cancer. Females, 24. Of the 38 abscess cases 2 died, one from suppurative nephritis, the other from septic peritonitis. The appendix was removed in all but 5 of the acute cases. One case of fecal fistula had not yet closed. In all the acute cases he followed the general plan of the smallest useful incision. He cleansed the abscess cavity with peroxide of hydrogen and salt solution, and sutured the abdominal walls separately and accurately. In his hands he thought the use of gauze packing and opium would probably have lessened the favorable results. None of his cases without abscess had died or had had post-operative hernia. In two cases the appendix had become twisted upon itself, narrowing the lumen, which was distended with mucus. He had made it a rule on arriving at a diagnosis of appendicitis to operate, no matter what the stage. The appendix was like a cap which might snap and cause an explosion, and nobody could tell in advance just what might happen in a particular case.

Appendicitis and Rheumatism.—DR. BEVERLY ROBINSON said he believed to-day even more strongly than he did about two years ago, when he expressed the opinion for publication, that in many instances the only correct interpretation of appendicitis was the recognition of an underlying rheumatic condition. He did not wish it understood that he was opposed to surgery: he believed that at a certain stage of the dis-

ease it was the only means of saving life. But before that stage had arrived many patients could be cured by anti-rheumatic treatment, just as many cases of tonsillitis responded to such treatment when without it local measures seemed ineffectual. Salicin, salol, salicylic acid, etc., were the efficient remedies in this class of cases. He believed the latest anatomical investigations showed a large amount of lymphoid structure in the cæcum, more especially in the appendix. This pointed to similarity of structure with the tonsils, which were known to reflect the rheumatic tendency. Mild laxatives, not active purgatives, were beneficial. Opium was harmful, not only because it obscured the symptoms, but also because it dried up the secretions. He felt certain that by acting on these suggestions many cases of appendicitis could be checked before the stage of suppuration and sepsis.

DR. GIBSON said Dr. Morris' results, only two deaths in one hundred, none of post-operative hernia, seemed wonderful. He did not think it was due to the method of operating. It looked as though he had had a hundred cases the great majority of which were easy ones. The statement that there had been no case of hernia was remarkable, and it suggested the question whether he spoke of hernia in the same sense that another practitioner might. His method of closing the abdominal wound was not different from that practised by other good surgeons, who, nevertheless, had reported some cases of hernia.

Simple Cases.—THE CHAIRMAN, on analyzing the paper, found that in only thirty-eight cases was there abscess, a few of malignant disease. The remainder of the one hundred cases were practically operations on the non-infected peritoneal cavity, similar to removal of a slightly diseased ovary. It was not so remarkable, therefore, that the death rate had been low. Freedom from hernia might be explained in the same way. The wound could in most of the cases be closed readily by primary suture.

DR. HOWARD LILIENTHAL presented a piece of wood a third of an inch long, of the diameter of a match, which he had found in a fecal concretion within the appendix. The tip of the appendix had been perforated but the wood had not found its way out. Regarding treatment, he thought that when an acute case of appendicitis had been proven to be progressive it should be operated upon. Anti-rheumatic treatment might be tried in chronic cases, but not longer than a few hours in acute ones.

DR. A. L. FISK said the object in operating in appendicitis was to save life, and since to close an abscess cavity here was more dangerous than to allow union by granulation he thought it was not justifiable simply to diminish danger of hernia. Suppose hernia should occur. Good surgeons could now effect radical cure almost invariably, as shown in the practice of Halsted and Abbe. So far as he had been able to learn, there was no more lymphoid tissue in the appendix than in the rest of the intestinal tract, so that this argument in favor of the rheumatic theory seemed ill founded. The incision should be large enough to suit the case.

THE CHAIRMAN agreed with Dr. Fisk that the size of the incision should depend upon the circumstances of the case. Often one required the aid of sight as well as of touch for the safety of the patient.

Excision of the Tongue for Malignant Disease by Electro-Surgical Means.—DR. D. H. GOODWILLIE read some general remarks on malignant disease of the tongue and then showed some electrical instruments for removal of the organ. He preferred the electric cautery wire loop and knife to the cold knife, because of less hemorrhage and of destruction by the heat of any stray cancer cells in the path of the instrument. The lingual arteries were tied before excising the tongue. In some cases removal of half the tongue was practised.

Dr. Fisk thought surgeons were becoming more and more convinced of the necessity of thorough removal of malignant disease of the tongue, including the glands, just as was done by the Halsted and Meyer operation on the breast. Statistics showed poorer results from the *écraseur* than from the knife and scissors.

DR. CURTIS thought the objection to the *écraseur*, that it left the glands in place, was well taken. Personally he had not seen a case of cancer of the tongue early enough to prolong life more than a year, even by removing glands along with the tongue. Kocher's operation was much more ideal than the cautery, and the wound left in the mouth healed within a few days.

Gastro-Enterotomy for Carcinoma of the Pylorus.—DR. GEORGE E. BREWER presented a specimen consisting of a part of the stomach and jejunum, showing good union six days after suture anastomosis performed for obstruction of the pylorus by cancer. The man had done well after the operation for six days and then went into collapse and died, presumably of cerebral embolus, for there was an old heart lesion.

Sarcoma of Tibia Following Injury.—DR. A. L. FISK presented a specimen, consisting of the amputated leg of a girl of fifteen, removed the same day by Dr. Abbe for sarcomatous tumor of the upper portion of the tibia. There was no family history of malignant disease, syphilis, or tuberculosis, and no other apparent origin except a trauma some months before.

Dilating Forceps.—DR. JOHN B. WALKER presented a strong forceps, with long handles, blunt blades, removable cone-shaped hood with probe-like handle. The hood permitted easy introduction of the forceps through a vaginal or other opening; the hood could then be lifted off and the opening dilated by the forceps.

Artificial Shoulder Joint.—DR. E. A. BOGUE showed an ingenious artificial upper portion of the humerus and shoulder-joint, fastened by screws to the lower half of the humerus and to the scapula. It had been worn by a patient of Péan's in Paris for two years and a half, the upper end of the humerus having been removed for tuberculous disease. It was then removed, and strangely enough bone re-formed and the man had a useful arm.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 11, 1895.

GEORGE P. BIGGS, M.D., PRESIDENT.

Glioma (?) of the Medulla.—DR. JOSEPH COLLINS presented a specimen removed from a man who had been recently admitted to the City Hospital to the service of Dr. J. E. Kelly. The man was a bricklayer, about thirty-five years of age, who eight months ago had noticed a numbness in the index finger and thumb of the left hand. Shortly after this, this numbness had extended up to the shoulder. Two or three months later a similar sensation had been noticed in the left foot and had gradually extended up to the thigh. He had kept at his work until about four months before his admission, when he had found that his movements had become so unsteady that he could no longer work at bricklaying. He then worked for a short time in a fur factory. He denied having had syphilis and was exceedingly temperate in his habits. He had never had any headache, any disturbance of vision or vomiting; hence the cardinal symptoms of cerebral tumor had not been present. He complained, however, of a peculiar sensation in the left side of the head—a feeling of pressure on that side. There was considerable ataxia of the left arm and leg. Examination showed exaggerated knee jerk on the left side and ankle clonus on that side; some acceleration of the

knee jerk on the right side, but no ankle clonus. There was no loss of muscular sense nor of tactile sense, but there was, strange to say, a universal analgesia involving even the mucous membrane of the pharynx, of the larynx, and probably also of the bladder. There was no difficulty in speech, no apparent difficulty in swallowing, and no affection of the cranial nerves could be made out. His mental condition was excellent. It had been supposed that the universal analgesia was nothing more than an expression of a psychological difficulty; the other symptoms had been supposed to indicate a lesion in the motor tract somewhere beneath the gray matter. As there had been no convulsions, the lesion could not have been in the gray matter. The man died as a result of a rapidly developing pulmonary œdema. On account of this pulmonary œdema and some hebetude it had been thought that there might be an increased distention of the ventricles, and it had been considered advisable, therefore, to make an exploratory opening and pass a needle into the ventricles. A needle had been introduced in various directions but no fluid had been found. At the autopsy the brain had been found practically intact, but on examining its under surface it was found that the medulla was enormously enlarged. On cutting through the medulla it was found that a tumor occupied the centre of the medulla and seemed to have replaced almost all of the medullary tissue, with the exception of a thin shell-like covering. Dr. Van Gieson had carefully examined this tumor and had expressed the opinion that it might be a gliomatosis of the central canal, with resulting infiltration, or possibly a tubercle.

Multiple Tumors of the Cerebrum.—Dr. Collins also presented a brain removed from a little girl who had been in the babies' wards of the Post-Graduate Hospital. The history was that after a protracted diarrhœa the child had passed into a stuporous condition and finally into a cataleptoid state. The child had been examined at Dr. Dana's clinic and a loss of light reflex and accommodation reflex had been found, but this was the only cranial nerve palsy that could be detected. A probable diagnosis had been made of a tumor of the basal ganglia. There was no enlargement of the head, no optic neuritis, nor anything to indicate distention of the ventricles. The condition of hebetude deepened and the child eventually died, apparently from inanition. On the basal surface of the left cerebellar lobe a small, whitish tumor was found, apparently connected only to the pia. It was also found that the head of the caudate nucleus on the right side was the seat of a similar new growth. A third new growth, and the one which had produced the symptoms, was found to involve the anterior and posterior quadrigeminal bodies.

Dr. F. S. MANDLEBAUM, referring to the first specimen, asked if the cord had been examined and if any gliomatosis had been found in the cord.

Dr. COLLINS said that the cord had been examined and that the tumor seemed to terminate abruptly at the lower part of the medulla. There appeared to be positively no gliosis at the upper termination of the cervical cord.

THE PRESIDENT remarked that the location of the third tumor described in the last case was similar to one recently presented by Dr. Nammack to the New York Neurological Society.

Uterus of a Dog Strangulated in the Inguinal Canal.—Dr. F. S. MANDLEBAUM presented a uterus from a small black-and-tan dog about five years old. The dog had had what appeared to be inguinal hernia. The animal had become pregnant and very shortly after this the inguinal tumor had begun to enlarge. The dog died three weeks afterward, with high temperature and symptoms of sepsis. At the autopsy it

was found that both horns of the uterus were prolapsed into the inguinal canal and strangulated there, being held in place by firm adhesions. Both horns were greatly enlarged and on section were found distended with thick and offensive pus. No trace of any embryo could be found. The purulent matter extended down the tubes and into the uterus. The speaker raised the question as to whether the strangulation of the tubes which had prolapsed into the inguinal canal was sufficient to cause this or whether there had been some infection; and if so, what was its source?

A New Clearing Medium.—Dr. HENRY POWER said that about a year ago Dr. Piffard had introduced a new clearing medium having the high refractive index of 1625. After some experimentation, the speaker said, he had obtained a very satisfactory clearing medium by mixing isosafrol and mono-bromide of naphthalin in the proportion of one to five. This possessed the same index of refraction as Piffard's medium. It would not mix properly, however, in celloidin, hence it was necessary to pass the specimen into one of the other oils and then into the new clearing medium.

Dr. IRA VAN GIESON said that Dr. Piffard's medium could not be used in many fine researches because it faded the aniline stains.

Dr. POWER replied that his was not a mounting but a clearing medium. He had allowed eosin and hamatoxylin specimens to remain for three weeks and no color had been extracted, and he had also kept bacteria stained with fuchsin in Piffard's medium for over six months, without any change whatever.

Portion of Bowel Discharged per Rectum.—Dr. F. FERGUSON presented a section of the intestine which had sloughed off and been passed per rectum in a case of intestinal obstruction occurring in a boy of four years.

Mounting the Appendix Vermiformis.—Dr. Ferguson also exhibited a novel and inexpensive method of mounting specimens of the vermiform appendix. The specimens were placed in glass tubes containing the preservative fluid, and these tubes were sealed with beeswax and mounted in an inverted position in circular blocks of wood. The specimens when mounted in this way required little or no support, and the magnifying effect of the ordinary vessels was avoided.

Carbolic-Acid Poisoning.—Dr. GEORGE P. BIGGS presented specimens exhibiting the lesions produced by carbolic acid. The specimens had been removed from a woman about twenty-five years of age, who had been found lying in the street and who had died before reaching the hospital. The autopsy showed the characteristic lesions produced by carbolic acid. These were particularly marked in the stomach, duodenum, and upper eighteen inches of the jejunum. The duodenum was congested throughout, but active destruction of the mucous membrane was visible only in the upper portion. There was also found an acute œdema of the glottis. One kidney showed three large cicatrices and the other one such cicatrix. No lesions were found in the vessels or in the heart to explain these, and it was thought probable that they were of specific origin.

A Large Thymus Gland.—Another specimen from the same case was a large thymus gland, weighing forty-eight grams.

Large Biliary Calculus Causing Intestinal Obstruction.—Dr. Biggs also presented a large biliary calculus removed from a male sixty-eight years of age, who had been admitted to the New York Hospital complaining of vomiting and hiccough which had persisted for five days. The abdomen was very much distended. The urine contained a trace of albumin and large numbers of hyaline casts. For two days attempts were made to evacuate the bowels by cathartics

and high enemata, but without success. It was then decided to operate for the intestinal obstruction. A median incision was made in the lower part of the abdomen and a foreign body was found in the lower portion of the ileum which had produced complete obstruction of the intestine. The bowel was hurriedly incised longitudinally and on removal the foreign body proved to be a biliary calculus. It was pyramidal in shape, measured three and one-half by three centimetres, and weighed twenty-three grams. This peculiar shape indicated that the calculus had been formed in the gall bladder. The operation lasted twenty-five minutes. The man died the following day. At the autopsy the body was found extremely emaciated. The incision into the bowel was found to have been into the lower portion of the ileum. There was no leakage whatever at this point. The peritoneum was normal. The intestine above the point from which the calculus had been removed was still greatly distended and the bowel below this point still considerably collapsed. The gall bladder was surrounded by old adhesions which bound it to the liver and duodenum. The lungs were slightly emphysematous and were congested in their posterior portions. The kidneys were small and granular. The stomach was rather small, and the pyloric orifice in the fresh state only just admitted the little finger. There was no induration, however, at the pylorus. On passing the finger through the pylorus it was found that there was a large opening in the middle of the wall of the gall bladder which communicated with the first and second portions of the duodenum. It was through this opening that the calculus had passed into the intestine. On further examination of the intestine the jejunum was found very much congested and hemorrhagic throughout and there were small superficial ulcerations or erosions, which apparently had been produced by the pressure of the calculus in its passage. The contents of the jejunum were reddish-brown, while those of the lower portion of the ileum were of a clay color. A number of small calculi were found in the alimentary canal, which together weighed 2.5 grams.

DR. FERGUSON said that many years ago he had made an autopsy on an eminent clergyman, who had died after having suffered for eight days from intestinal obstruction. No effort had been made to relieve his condition. The autopsy revealed a calculus rather larger than the one just presented. One-sixth of this calculus has passed through the ileo-caecal valve, but the body of the calculus could not pass beyond this point. In another case, seen about five years later at St. Luke's Hospital, two calculi about three-fourths of an inch in diameter had passed through the adhesions that had been formed between the hepatic flexure of the colon and the gall-bladder. One of these calculi had actually perforated the wall of the cæcum. The speaker also recalled two cases in which the hepatic flexure of the colon had been united to the gall bladder and the opening had been found between the two, yet no calculus had been found. He had seen two other large calculi which had been passed by rectum whose size seemed to preclude their having passed through the ileo-caecal valve. The only explanation that he could offer was that the calculi had passed through an opening formed between the gall bladder and the hepatic flexure of the colon.

DR. POWER asked if there had been any evidence of exophthalmic goitre in the case in which there had been an enlarged thymus.

DR. BIGGS replied that there had been no previous history obtainable, but the eyes had not appeared prominent and the thyroid had not been enlarged.

The society then went into executive session.

Hair Restorer.—Great cry and little wool.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 8, 1896:

	Cases.	Deaths.
Tuberculosis.....	99	97
Typhoid fever.....	8	5
Scarlet fever.....	149	13
Cerebro-spinal meningitis.....	2	3
Measles.....	432	32
Diphtheria.....	306	35
Small-pox.....	1	0

The Food of American Laborers.—Dr. Moreau de Tours, in comparing American and European statistics of consumption of food, declares that the average French workman consumes less than one-half the amount of meat and nitrogenous food generally of the American, and that even in Great Britain, the most carnivorous of European countries, the individual consumption is less than two-thirds that of the American. In Germany, Austria, Italy, Spain, the consumption of meat is, as compared with the American, in the order named, and is from one-third in Germany to one-tenth in Italy, and in Spain infinitely less. The best-fed class of laborers, says Dr. De Tours, the world ever saw was the Southern negro in slavery times. Each adult received weekly three pounds of bacon or pork, ten pounds of farinaceous food (usually fresh corn meal), and vegetables of every species ad libitum. Each negro, then, says our author, consumed annually one hundred and fifty pounds of meat of a quality superior to that of any European people whatever, being from two to three times superior in point of nutritive value. To-day, while the supply is not so sure by any manner of means as it used to be, the Southern negro lives more luxuriously, not merely than any other laborer, but than the middle classes of any European nation whatever. Compared with like statistics of Asiatic peoples, the figures are absolutely startling.—*The National Druggist*, December, 1895.

Bacteria in Schoolrooms.—In a recent communication to the Hamburg Medical Society, M. Ruete details the results of his bacteriologic examination of the air of schoolrooms. He made use of Hueppe's method and made his investigations at 2:30 o'clock in the afternoons. While these were always made under the same conditions the results were very variable. He found a minimum of 1,500 bacteria to the cubic metre, a maximum of 3,000,000 and a mean of 268,000. Analogous researches gave Hesse an average of only 9,500. Among the bacteria observed the author calls attention (*Bulletin Médical de Paris*) to a motile bacillus which does not develop on agar, but on gelatin plaques gives rise to circular colonies with crenated edges; it can also be cultivated on milk and potato; pure cultures kill mice in twenty-four hours and their blood is rapidly fatal to guinea-pigs. Ruete has been able to extract toxins from the blood of animals thus killed.—*Journal of the American Medical Association*.

Syphilis through Flea Bite.—Jonathan Hutchinson reports a primary lesion of syphilis of unusual origin. An elderly member of the profession presented himself, covered with an evidently syphilitic eruption, which rapidly disappeared under the use of mercury. The only interest about the case was the question as to how the disease had been acquired. The doctor was evidently anxious to give all the information in his

power, but was positive that he had never been exposed to any sexual risk, and, as he had retired from practice, no possibility of infection in that manner existed. He willingly stripped, and a careful examination of his entire surface revealed no trace of lesion whatever on the genitals or at any point, except a dusky spot on one leg which looked like the remains of a boil. This the doctor stated had been due to a small sore, the dates of the appearance and duration of which were found to fit exactly with those of a primary lesion. There had also been some enlargement of the femoral glands. He had never thought of the sore in this connection but remembered most distinctly that it followed a flea bite in an omnibus, and had been caused as he supposed by his scratching the place, though he could not understand why it lasted so long. Mr. Hutchinson concludes that all the evidence tends to show that the disease had probably been communicated from the blood of an infected person through the bite of the insect. It thus appears that even the proverbially trivial flea bite may prove a serious injury at times.—*Medical News*.

Circular of Information Regarding Diphtheria Antitoxin.—The Health Department of New York City desires to direct the attention of physicians to some important modifications and improvements which have been made in the preparations of antitoxic serum which it is now able to furnish for the prevention and treatment of diphtheria.

As the result of some investigations carried on in the bacteriological laboratory of the Health Department, which have greatly perfected the methods of production of diphtheria antitoxin, it has been possible to prepare antitoxic serum of much greater power than that which has previously been in use. The curative value of any preparation of antitoxic serum is, of course, due not to the amount of serum but to the amount of antitoxin which the serum contains, and investigations seem to show that the disagreeable symptoms sometimes occasioned by the use of diphtheria antitoxin are due, not to the antitoxin but to the horse's blood serum in which the antitoxin is present in solution. It naturally follows that more concentrated preparations, in the use of which only small doses are required (2-5 c.c.) will diminish materially the frequency with which the rashes and other symptoms follow the administration of the remedy. The preparations of antitoxin hitherto furnished by the Health Department are known as Nos. One, Two, and Three (Behring's standard), and correspond to Nos. One, Two, and Three of Behring's preparations. No. One contains sixty (60) antitoxin units to each cubic centimetre of the serum, or six hundred (600) units in each vial. No. Two contains one hundred (100) antitoxin units to each cubic centimetre of the serum, or one thousand (1,000) units in each vial. No. Three contains one hundred and fifty (150) antitoxin units to each cubic centimetre, or fifteen hundred (1,500) units in each vial. The Health Department is now able to furnish much more concentrated preparations than No. One and No. Two, and has, therefore, decided to discontinue the preparation and use of these weaker serums. Hereafter diphtheria antitoxin will be furnished in the following grades and amounts:

Grade No. 3. Vials contain 10 cubic centimetres, 150 antitoxin units (Behring's standard) to each cubic centimetre, or 1,500 units, \$1.50.

Grade No. 3a. Vials contain 5 cubic centimetres, 150 antitoxin units (Behring's standard) to each cubic centimetre, or 750 units, \$0.75.

Grade No. 4. Vials contain 5 cubic centimetres, 200 antitoxin units (Behring's standard) to each cubic centimetre, or 1,000 units, \$1.25.

Grade No. 5. Vials contain 5 cubic centimetres,

300 antitoxin units (Behring's standard) to each cubic centimetre, or 1,500 units, \$2.00.

Grade No. 6. Vials contain 5 cubic centimetres, 400 antitoxin units (Behring's standard) to each cubic centimetre, or 2,000 units, \$3.00.

It is at once apparent that preparations of antitoxic serum which contain a large amount of antitoxin to each cubic centimetre are more desirable than those containing a smaller amount, as the dose required is proportionately less and the disagreeable symptoms following its use will be relatively less frequent. The highest grade preparations, however, are much more difficult to produce, are necessarily more expensive, and at present, even with approved methods, can be produced only in limited quantities; therefore, the department, as before, furnishes the serum in a number of different strengths at prices as nearly as possible at cost. The average curative dose of diphtheria antitoxin is about one thousand (1,000) units, but for very severe cases or croup cases, or those in which the serum is not administered until the third day or later, fifteen hundred (1,500) or two thousand (2,000) units are often required, and sometimes the dose must be repeated, so that altogether from four to six thousand units may be required in a single case. Full directions as to the use of the serum accompany each vial. The new preparations of antitoxic serum will be gladly furnished, as heretofore, without charge to all public hospitals, dispensaries, and charitable institutions in New York City on application, and it can be obtained free by physicians at most of the depots established for the supply of diphtheria culture tubes, for use among those persons who are too poor to pay for the remedy. In such cases the physician in attendance is required to fill out a blank, to be obtained at each of the stations, giving particulars in regard to the case and the ultimate result of treatment. Medical Inspectors of the Health Department will also be sent on application to administer antitoxin to any case of diphtheria, under the supervision of the attending physician. The Health Department desires to encourage the use of antitoxin serum for the prevention of diphtheria, as the experience with its use for this purpose has been most satisfactory. From one hundred (100) to three hundred (300) units, according to age, are required to confer immunity. The immunity thus produced ordinarily lasts for a period of at least four weeks. With the new and strongest preparations of antitoxic serum only very small quantities of serum (from six to fifteen minims) are necessary for the production of immunity.

THE TREATMENT OF HYPERPYREXIA (HIGH FEVER) IN CHILDREN, WITH SOME ILLUSTRATIVE CASES.

By LOUIS FISCHER, M.D.,

ASSOCIATE PROFESSOR OF PEDIATRICS, NEW YORK SCHOOL OF CLINICAL MEDICINE; ATTENDING PHYSICIAN, MESSIAH HOME FOR CHILDREN; ATTENDING PHYSICIAN, CHILDREN'S DEPARTMENT, GERMAN POLIKLINIK.

IN the *Post-Graduate* of July, 1893, will be found a paper entitled "The Treatment of Hyperpyrexia in Pneumonia of Children," which was read by me before the Clinical Society of the New York Post-Graduate School, January, 1893. My observations were based on a series of cases which had been attended by me from time to time, but more particularly on two distinct cases occurring in the babies' wards of the Post-Graduate Hospital. The depressing (cardiac) effects of all antipyretics are so well known that most practitioners who use them do so very cautiously. In some instances, where antipyrin has been combined with either camphor or musk, it was in order to overcome this depressant action. It is for this reason, and especially for the well-known cyanosis that occurs in the use of antifebrin, that I have been led to do away with the antipyretic treatment by the aniline drugs in children. Several thousand children seen by me during the course of years at the German Poliklinik have convinced me that we do not require an antipyretic drug excepting in very rare instances, for, on considering the real cause of hyperpyrexia, we look to treating the cause rather than its effect, which in reality is the fever. It is a well-known fact that children can bear higher temperatures better by far than adults. Besides, a prolonged fever in children is a daily occurrence. The slightest irritation of the stomach or of the intestines or of the bronchial mucous membrane, the slightest infection in the tonsil or pharynx or in a lung, will give rise to very high temperatures. It is therefore of the utmost importance to make a diagnosis and then to treat the disease and not its symptom, which in most instances is fever.

There are, however, exceptions to this rule, and while some children can stand a temperature of from 103° to 104° F., and, as in an acute gastritis, you will sometimes find a temperature of 105° F. and even higher, there are times when fever must be reduced and a threatened convulsion aborted. There is hardly a physician who has not been called to see a child in the midst of a convulsion ending fatally, and with a temperature of 105° F., that might not have been saved had the proper treatment been instituted prior to the convulsive attack. It is in these cases that we stop to think whether it is advisable to treat first the most dangerous symptom, which is the high fever, or rather the cause of the trouble and to remove that if possible. So, for example, when we find the well-known septic gastritis, due to an overloaded stomach, it can be best treated by an ordinary warm saline irrigation, and we can, by removing the offending cause, reduce the temperature at times from 105° F. to an almost normal condition within from half an hour to

a whole day, by a simple thorough cleansing of the alimentary tract. This can be done when the stomach is affected and where we have direct access to the seat of the disease.

But if a temperature of 105° F. is caused by a consolidated lung, the treatment instituted must be different. Here, as stated in the previous sentence, we have not direct access to the lung, as we had above to the stomach, and therefore we must determine by reasoning what sort of treatment to institute. Henoch, in his edition of 1890, page 385, speaks of the treatment of pneumonia and of the depressing action of antipyrin and antifebrin not only on the general nervous system, but more especially on the heart, and as antipyretics act but a short time, *the danger lies in the constant repeating of each dose and its adding to the already existing cardiac weakness*; therefore Henoch strongly advises the use of cold applications externally, and recommends the hydropathic treatment accordingly. Baginsky, in 1892, gives a similar report, and so we find in Unger's "Diseases of Children," 1890, on page 193, an endorsement of the previous treatment. In Pepper's "System of Medicine," Alfred L. Loomis in "The Treatment of Croupous Pneumonia," page 349, speaks of the value of the full-length bath if the temperature rises above 103° F. Dr. S. Baruch, of this city, is most enthusiastic as to the treatment of most diseases by hydrotherapy, owing to this depressing effect of antipyretics on the heart. I have, therefore, basing my course on the statements of so many clinical observers and on my own experience, relied until a very short time ago upon the antipyretic treatment of a gradually cooled bath.

In looking over our very recent literature we find, in the *Louisville Medical Monthly* for November, 1895, an article entitled: "Cyanotic Symptoms after Local Applications of Acetanilid," by Charles Sauter, M.D. He treated a child that had a slight eczematous eruption on the neck, and after using some acetanilid locally cyanosis appeared. The doctor states that he found the child blue, breathing heavily, and showing such other symptoms of distress, that he thought it advisable to discontinue the powder.

In the *Berliner klinische Wochenschrift*, No. 46, November 18, 1895, is an article, "Aus der inneren Abteilung des städtischen Krankenhauses am Friedrichshain in Berlin, Phenacetin Vergiftung mit tödlichem Ausgang," by Prof. Dr. G. Krönig. In this very elaborate paper, which the author read before the Verein für innere Medizin for that year, he relates in detail his experience with a patient, seventeen years of age, whose lips were blue, pulse on the radialis small and intermittent, respiration 32, and presenting a series of other symptoms, in which, after a careful examination of the blood to determine the percentage of hæmoglobin and, besides, the blood corpuscles, he found a distinct "erythrolyse." The clinical history is interesting, because the patient received five phenacetin powders, each containing one gram (fifteen grains); no more than two powders were to have been given. The assistant noticed a peculiar pallor of the patient soon after the drug was taken. The urine was chocolate colored; the body had a yellowish coloration.

tion; and a cyanotic condition of the lips, ears, hands, and feet appeared. The diagnosis of phenacetin poisoning was made.

In conclusion the author states that Hinsberg and Kast found that in experiments on dogs, two to three hours after phenacetin had been given, the respiration was interfered with, there was sleeplessness, vomiting, and a blueness of the mucous membrane of the mouth. A spectroscopic examination showed the presence of methemoglobin.

Experiments on healthy, not feverish, people prove that after taking one gram of phenacetin, headache, dizziness, trembling of the limbs, and interference with locomotion are produced.

Dr. von Jaksch found, in experiments on children, intense cyanosis, profuse diaphoresis, and frequently symptoms of collapse, where a dose of but one to two decigrams (one and a half to three grains) of phenacetin had been given. He believes phenacetin to be more dangerous than antifebrin.

In the literature of this subject a great many eruptions are reported resembling an urticarious exanthema, as also irritation and dryness in the throat, and the digestive track shows symptoms of pyalism, eructation, vomiting, and diarrhoea.

Cattani found a toxic hæmaturia and nephritis, where a dose of six grams (ninety grains) phenacetin pro die had been given.

Prof. A. Frankel, in the discussion of this paper mentioned that he had seen serious effects following the taking of one-half gram (seven and one-half grains) of phenacetin. A seventeen-year-old actress died after taking one gram (fifteen grains) of phenacetin.

Professor Fürbringer spoke of the necessity of giving very small doses. Dr. Hans Aronson mentioned the fact that in a series of experiments performed by him in 1889 under Ehrlich's supervision with phenacetin and its derivatives serious symptoms manifested themselves.

Professor Gerhardt mentioned the fact that he used phenacetin, antifebrin, antipyrin, and phenocoll in articular rheumatism, and found severe symptoms and collapse. The only drug that the author thought had any moderating effect was lactophenin in doses of one-fourth gram (four grains).

There is considerable literature relative to the serious incidental and after effects which sometimes accompany or follow the remedial action of acetanilid, otherwise known as antifebrin. The substance is not to be recommended for external application as an antiseptic.

In Helbing's "Modern Materia Medica" will be found an interesting discussion on antipyrin. However, on page 9, the author states (I will use his own words):

"It may be mentioned that the latest observations of the action of antipyrin have led to the expression of the opinion by several authorities that it has a marked and in some instances dangerous action on the heart, producing lowering of blood pressure, malaise, and collapse, according to Drache. To this action must be ascribed the fact that antipyrin, which was used almost as a specific against influenza during the earlier epidemics, was almost abandoned during the later. Against the copious perspiration that frequently accompanies the action of antipyrin, atropine or agaricin is given, either at the same time as the remedy, or shortly before it, according to Von Noorden. In certain cases it seems that the antipyrin has a tendency to cause nausea and sickness, if taken internally."

During the last few years a number of headache powders have been introduced, which are taken by the public without discrimination. They contain mostly acetanilid, its very low price being an inducement to manufacturers of nostra to employ it extensively in their preparation.

According to Helbing's "Materia Medica," a number of American antipyretics, such as antikamnia, phenolid, exodyne, etc., are all mechanical mixtures containing acetanilid, and though we do not deny their value, the physician prescribing such remedies is not aware of the porportion of acetanilid contained therein.

A remedy having the powerful physiological effects of acetanilid should certainly not be employed without the advice of a physician. In Germany, for instance, migrainin, phenacetin, antipyrin, and antifebrin (acetanilid) cannot be obtained without a prescription.

According to the *Times and Register* of November 23, 1895, the new antipyretic ammonol consists of acetanilid and ammonium carbonate.

In the *Allgemeine Medicinische Central-Zeitung*, Nos. 60 to 62, 1895, will be found a report on a new antipyretic and analgesic called apolysin, which had been submitted by Dr. F. von Heyden, successor in Radebeul to Prof. M. Von Nencki in the St. Petersburg Institute for Experimental Medicine, as well as to Drs. Leo von Nencki and Jos. von Jaworski of Warsaw. A series of forty-two cases in which the drug has been used gives very gratifying results. It may be proper to state that apolysin is a yellow-white crystalline powder of a slightly sour taste, not so sour as citric acid, soluble in the proportion of one in fifty-five in cold water, exceedingly soluble in every proportion in hot water, and melting at a temperature of 161.6° F. It is also very soluble in alcohol and in cold glycerin. In concentrated sulphuric acid it is soluble without adding color to the solution. In concentrated nitric acid apolysin is also soluble and the solution on being warmed turns a light orange color. An apolysin solution in concentrated sulphuric acid, in the proportion of one decigram of apolysin to one cubic centimetre of acid, gives, on heating with ten volumes of distilled water, a ruby-red color when crystals of chromic acid are added to it. When apolysin is heated on a small platinum sheet, it burns without leaving any ash, which proves that it contains no mineral ingredients. On the addition of a silver nitrate solution, a watery solution of apolysin does not give a precipitate. With sulphate of ammonia it does not give a precipitate, which also proves the absence of metals. As the chemical constitution of apolysin is analogous with phenacetin, it is believed that this substance is also similar in its pharmaco-dynamic action. We know a great many remedies, which have been examined chemically and clinically, and prove a similarity, as do the two preceding substances; so, for example, chloroform and chloral, ethylene chloride and ethylidene chloride, which are closely related chemically, show also similar pharmaco-dynamic actions. Apomorphine and methyl morphine, both derivatives of morphine, show the same therapeutic healing actions, although different from morphine.

Prof. M. von Nencki has proved in one of his papers "The Influence of the Carboxyl Group (COH₂) upon the Toxic Action of Certain Bodies of the Aromatic Series," and also the dependence of the pharmaco-dynamic action upon their chemical constitution.

Benzol and its derivatives, naphthalin, phenol and its derivatives, aniline, pyridin, chinolin, act more poisonously on our bodies than do benzoic acid, naphthalin carbonate, pyridin carbonate, chinolin carbonate, etc. Besides, von Nencki proved the so-called dependency law of a number of antipyretic and analgesic actions of a great many bodies which are used in medicine to-day, as for example, acetanilid (antifebrin), phenacetin, antipyrin, etc.

Recently G. von Treupel in the *Deutsche medizinische Wochenschrift*, No. 14, 1895, gives the result of the action of para-amido-phenol and para-acetamidophenol when introduced into the veins. The dose of

one to two grams per kilogram of body weight produces quickly clonic and tonic convulsions, difficulty of respiration, and paralysis of certain motor centres, but does not affect the reflexes. In the dose of half a gram to a kilogram of body weight in a dog these two substances produce somnolence, weakness in the hind legs, cyanosis, and vomiting. The salivary secretion is increased and in the blood methæmoglobin is produced. When introduced into the human organism para-amido-phenol, as also para-acetamido-phenol, in doses of half a gram, reduces the temperature between 3.6° and 5.4° F., the reduction being accompanied by a chilly sensation, and at times by vomiting and also tinnitus aurium. When in the para-amido-phenol group we substitute alkyls in place of the hydrogen of the hydroxyl group, such as methyl, ethyl, propyl, we retain the antithermic properties of the mother substance, whereas the toxic constituent is decreased. Of all antipyretics the methyl group possesses the maximum properties, while the smallest toxicity is found in the similar bodies of the ethyl group. By substituting for the hydrogen in the amide group an alkyl of the para-acetamido-phenol group we produce substances which act strongly antipyretic and narcotic. The highest narcotic action is found in the methyl group, which diminishes with the increase of the alkyl group; the least toxic are those found in the ethyl group.

All the previously mentioned bodies are split up in the animal body and yield para-amido-phenol or para-acetamido-phenol. When, however, we substitute in the para-amido-phenol one hydrogen atom of the amide group (NH_2) by ethyl, the resulting body is liberated and possesses neither antithermic nor analgesic properties. The antithermic action of the phenacetin derivatives depends upon the liberation of para-amido-phenol or para-acetamido-phenol, whereas the narcotic effect is produced by the splitting up of the substances contained in the alkyl group. As disagreeable symptoms sometimes accompany the quick splitting up of these substances, it has been customary to prohibit giving them on a stomach containing only free hydrochloric acid which has not been neutralized by the introduction of food.

In conformity therewith it has been found:

1. That apolysin is not poisonous.
2. That it is split up in the human organism into para-amido-phenol and para-phenetidin, ethyl, and citric acid, which, as is well-known, are oxidized into carbonic acid and water.
3. That para-amido-phenol and para-phenetidin, *i.e.* the group in which one hydrogen atom of the amides (NH_2) is substituted by citric acid, produces lower temperature, whereas the ethyl has the analgesic action.
4. That the substances are found in the urine either as glycuron combinations or as sulphate salts, which can be proved by chemical examination.

In the *Centralblatt für Bacteriologie und Parasitenkunde*, No. 19, 1895, will be found an interesting article entitled: "Ueber das Verhalten des Apolysins gegenüber dem Typhus Bacillus," by Bezirksarzt Dr. W. Hesse, of Dresden. In this are presented a series of experiments carefully conducted with a view to determining the value of apolysin as compared with drugs like phenacetin, lactophenin, etc., besides their action on the typhoid bacillus.

In the *Centralblatt für innere Medizin*, November 9, 1895, also will be found an interesting article entitled: "Ueber Apolysin und Citrophen nebst Bemerkungen über die praktische Verwendung von Phenetidin-derivaten," by Dr. H. Hildebrandt, of Elberfeld. A series of experiments on white mice and dogs was made, in order to determine the relative toxicity of citrophen as compared with apolysin. The author concludes by saying that apolysin is a much quicker an-

tipyretic and analgesic than phenacetin, and praises its great solubility. Used in subcutaneous injections it was found to be far less poisonous than phenacetin: eight centigrams (one and one-fourth grains) of apolysin were found to be quite easily tolerated in white mice without producing any after-effects, whereas three centigrams (two-fifths grain) were sufficient to show a phenetidin reaction when phenacetin was injected.

Another paper by Dr. A. Seifert has also appeared in the *Deutsche medicinische Wochenschrift*, No. 44, 1895, in which this author distinctly says that apolysin is free from every toxic effect.

In order that I might test the value of this new drug, a series of cases was taken of children suffering from high fever in various diseases. For example, cases of pneumonia (cerebral) and typhoid fever, rheumatism, measles, and others were taken.

Some of these children belonged to the Messiah Home; by far the greater number were from the children's department of the German Poliklinik. Let me illustrate a few typical cases:

CASE I.—C. M——, fourteen years of age, November 8th, came to the German Poliklinik with the history of having had a fever during nine days preceding. Pains were present in the whole body, more particularly the limbs, with intense headache and thirst; there was vomiting at times and diarrhoea. The color of the stools varied from yellow to green; they were semi-solid, foul smelling. The patient had no appetite, slept heavily, and could not see well.

Physical examination: Small, lenticular spots, disappearing under pressure; a typical roseola on the abdomen and scattered over the thorax. There was an enlarged spleen. The lungs, heart, and liver were normal. The tongue was quite brownish-white. Some sordes on the teeth. The pupils of the eyes appeared to be normal.

Diagnosis of gastritis typhosa was made. D. Krobike at my direction washed the stomach with a gastric irrigator, and gave apolysin, 0.3 gram ($4\frac{1}{2}$ grains), every hour. Temperature was 105° F. in the mouth, pulse 146, respiration normal. The examination was conducted in the presence of Dr. Joel, Dr. Groehl, and Dr. McConville.

November 9th.—There was a typical exanthema, temperature 104° F.; the temperature fell two degrees after giving ten grains of apolysin.

November 10th.—There were typical green stools; headache had been greatly relieved by the apolysin. There was no effect on either heart or pulse; the latter was regular and full, with no intermittence. The largest dose given was 0.5 gram ($7\frac{1}{2}$ grains), twelve powders in twelve hours, without any evil result.

November 11th.—The temperature was 102° F., and continued at 102° F. for the next eight days, the lowest temperature in the morning being 100° F., the highest in the evening being $102\frac{2}{10}^{\circ}$ F. The disease ran its regular course; the boy recovered, and is at present (beginning of December) taking iron for its tonic effect.

CASE II.—F. W——, four years of age, was seen on October 31st, with the history of having been five days ill; could not walk; cried when the arms and legs were touched; was very feverish and thirsty. An examination of the body showed swelling of the joints, knee, elbow, shoulder, and ankle, on one side of the body (right); the temperature was 104.4° F.; there was shortness of breath, and on examination of the heart a loud blowing murmur was heard in front at the apex, transmitted to the side and heard behind a distinct mitral regurgitation. The diagnosis of rheumatism and endocarditis was made.

October 31st.—Temperature, 104.4° F.; apolysin, 0.3 gram, was given, and the temperature fell three degrees within two and a half hours.

November 1st.—Temperature, 103.4° F.; gave 0.3 gram ($4\frac{1}{2}$ grains) of apolysin; the temperature fell in two hours to 101.4° F.; ordered one powder every three hours.

November 2d.—Temperature, 102.8° F. at 11 A.M.; 0.3 gram ($4\frac{1}{2}$ grains) of apolysin was given and the temperature fell 2.4° F. and remained at 100.4° F. until the following day. I continued giving 0.3 gram ($4\frac{1}{2}$ grains) apolysin every three hours until the pains in the joints and the swelling subsided.

November 3d.—Temperature, 100.4° F.; November 4th, 100.2° F.; November 6th, 100.5° F.; November 7th, 100.6° F.; November 8th, 100.4° F.; November 9th, 99.4° F.

Although apolysin was given for ten days, there was no bad symptom that I could attribute to the effect of the drug; there was no diaphoresis, no cyanosis, nor any gastric effect.

CASE III.—Mary G.—, seven years of age; had had a cough for three days, with a fever, pain on breathing, and insomnia; temperature, 105.6° F.; pulse, 148; respiration, 68.

Status præsens: Cough simulating pertussis; no expectorations.

Physical examination: Dulness on left side anteriorly, and posteriorly complete consolidation and bronchial breathing; on the left side increased vocal fremitus. Diagnosis: croupous pneumonia.

At 11 A.M. and after I gave 0.25 gram ($3\frac{3}{4}$ grains) of apolysin every hour for three successive doses and then ordered a discontinuance of this drug for three hours; the temperature at 5 P.M., or about three hours after the last dose, was 102.4° F. I ordered a mixture of carbonate of ammonia every hour in doses of one teaspoonful; at 9 P.M. the temperature rose to 103.3° F. and did not go higher during the night. On November 2d, the following morning, at eleven o'clock the temperature was 103.2° F., pulse 132, respiration 62. The same physical signs were present on auscultation, percussion, and palpation; cough was about the same. The child appeared brighter. I again ordered apolysin, 0.2 gram (3 grains), for two doses, at intervals of two hours. At 5:15 P.M. the temperature was 102.8° F., pulse 134, respiration 59. The physical signs were unaltered and cough very severe. I gave carbonate of ammonia during the night.

Next morning, November 3d, at ten o'clock the temperature was 101.4° F., pulse 128, respiration 48. The physical signs were improved, and there was less cough. At 6 P.M. the temperature was 99.3° F., pulse 120, respiration 34.

November 4th, 11 A.M., temperature 99° F., and at five o'clock normal; the temperature had been taken in the rectum.

CASE IV.—G. W.—, six years of age, was seen at 1:30 P.M. He had vomiting, fever, and thirst, and the body had a rash which looked like an erythema. The question of exposure to scarlet fever was answered in the negative. Temperature was 105.2° F., pulse 140, respiration 29. There was no cough; the bowels were quite free, urine normal. No history of gastric fever was given.

I gave apolysin, 0.3 gram ($4\frac{1}{2}$ grains), every four hours. The temperature at 6 P.M. fell to 101.4° F. I discontinued apolysin, and at 10 P.M. the temperature rose to 103.3° F. The diagnosis of acute gastritis was made. The following morning there was no eruption, but there were pains in the body. The vomiting had ceased, and I gave one grain of calomel every three hours to cleanse the alimentary tract. The temperature was then 99.4° F. The child felt bright on the following morning, the temperature was normal, and appetite had returned.

CASE V.—Z.—, twenty-seven months old, was seen at the dispensary November 22d. The child

had bronchial breathing in right lobe, cough, and was very restless. Temperature, 105.8° F. Diagnosis: lobar pneumonia. Apolysin, 0.3 gram ($4\frac{1}{2}$ grains), was given every hour for four doses. The child was seen the same afternoon by Dr. Kobike. The temperature sank to 103.2° F.; he continued apolysin, however, every two hours.

The following morning, November 23d, the child's temperature was 103.2° F.; apolysin was ordered until four o'clock every two hours, 0.3 gram ($4\frac{1}{2}$ grains). At 6:15 the child was seen by Dr. Kobike, who found the temperature 100.2° F. Ordered a discontinuance of the apolysin.

November 24th, at 12 noon, the temperature was 99° F. The child made a rapid recovery.

CASE VI.—Frank U.—, four years four months of age, was seen November 21st. He had coughed about two days, and had fever, irritability, anorexia, and thirst; his temperature was 105.2° F. There was consolidation of the left lung, dulness on percussion, and bronchial breathing.

Diagnosis: lobar pneumonia. The case was seen at the Children's Department of the German Poliklinik and was sent home to be attended to at the house.

The child was seen the same afternoon and given an expectorant mixture (*mistura glycyrrhizæ compos.*) and an antipyretic bath ordered, consisting of immersing the child's body into warm water with a cooling of the bath from 95° to 79° F., leaving the child in the bath about ten minutes. An icebag on the head was ordered. The temperature in the evening was 106.2° F. I saw the case the same evening and ordered apolysin, 0.2 gram (3 grains), every hour.

November 22d.—Temperature, 104.4° F. at 10 A.M. Apolysin was continued, 0.2 gram (3 grains), every two hours. There were symptoms of general malaise, constipation, anorexia, and intense thirst. At five o'clock the same evening the temperature rose to 106.4° F. There was marked delirium and restlessness, and the child moaned. I ordered liquor magnesiæ citratis in order to quench the child's thirst and also to act as a laxative.

November 23d.—There was a consolidation on the left side of the lung and also on the right side. Temperature, 99° F. The bowels had moved quite freely. I gave apolysin, twenty-two powders in all. The dose was increased from 0.2 gram (3 grains) to 0.3 gram ($4\frac{1}{2}$ grains) every hour. As the temperature was 99° F., I ordered a discontinuance of the drug. Dr. Kobike saw the child at 6 P.M. and reported to me that the temperature had risen to 107.2° F. I immediately ordered apolysin, 0.3 gram ($4\frac{1}{2}$ grains), every hour for the night. The child slept somewhat. I ordered an ice bag on the head and saw the child.

November 24th.—The temperature in the morning, at eleven o'clock, was 101.4° F. There were sonorous râles on the right side, the left side was clear. Consolidation was manifest on the lower lobe of the right side, with anorexia and brown dry tongue. The child had had one green stool. The urine was scanty, and there were distinct evidences of a typhoid pneumonia, with marked delirium, subsultus tendinum, and sordes on the teeth. Temperature at 6:30 P.M., taken by Dr. Kobike, was 106.2° F. I saw the case two hours later and found a temperature of 107.4° F.; I ordered an antipyretic bath every two hours, besides apolysin, 0.3 gram ($4\frac{1}{2}$ grains), every two hours; later I ordered, on one hour a bath and on the other hour apolysin, with ice bag on the head. The temperature fell to 103.8° F. at 3 A.M.

November 25th.—At 10 A.M. an examination of the child showed bronchial breathing and friction sounds, and the pupils did not react to the light; there were still evidences of a typhoid condition—a brown

tongue and intense thirst. The bowels had moved; the urine was scanty. There was slight delirium; the temperature at 10 A.M. was 99.8° F. I ordered a discontinuation of the apolysin and then gave an expectorant, besides a liquid enema. The temperature at 2 P.M. was 105° F.; at 6 P.M., 106.4° F.; pulse, 140; respiration, 38. At 9 P.M. the temperature was 105° F., and at 10 P.M. 103.8° F., which was the lowest temperature of the night.

November 26th.—The temperature had risen to 105.4° F. at 10 A.M.; pulse, 148; respiration, 64. The chemical examination showed an excess of phosphates and an enormous amount of uric-acid crystals. There was no albumin, no blood, and no pus. There was still the same comatose condition, with delirium, complete consolidation of both lungs, and a double pneumonia. Diagnosis: pneumonia cerebri. At 2 P.M. the temperature, taken by Dr. Kobike, was 104.4° F.; at 6 P.M. the temperature, taken by myself with Dr. Kobike, was 106° F.

November 27th.—During the night the temperature, taken by a trained nurse, had remained between 104° and 105° F.; pulse, 146; respiration, 64. There was still photophobia, the consolidation in both the lungs was still plain, and there was cough. The pupils were enormously dilated. Sordes were apparent on the teeth. The child was comatose most of the time, and nourishment by mouth could not be given. He had no desire to drink, and we could resort only to nutrient enemata. Since the night before we had been resorting to egg emulsion and, besides concentrated liquid foods, a somatose emulsion. The ice bag was on the head continuously. The urine was examined twice for the presence of the sulpho-diazo-benzol reaction of Professor Ehrlich, and responded very plainly, so that the diagnosis of typhoid by the examination of the urine was easily corroborated.

November 28th.—The temperature had fallen to 102° F., the physical signs were clearing up, consciousness was returning, and the child suddenly craved drink and liquid food. The cough had become very loose, and expectoration quite copious. There was at times a tendency to vomit after frequent attacks of cough. The bowels were extremely loose, and the child presented the condition of convalescence.

November 29th.—Temperature, 99° F. at 10 A.M., and 100.4° F. at 6 P.M. The typhoid symptoms were disappearing. The child had commenced to retain food, and the nutrient enemata were discontinued. The urine was more abundant, the expression healthier. Convalescence continued, and the case was discharged cured December 24th. The child had become considerably emaciated since the commencement of treatment.

CASE VII.—J. H.—, twenty-eight years of age, had been infected with measles about two weeks previously from a child in the same house. When I saw him, he had been coughing and sneezing, and had conjunctivitis catarrhalis and bronchitis—in fact, the usual symptoms of morbilli. The temperature was 104° F. in the mouth, and there was a slight eruption on the face and neck.

On the following day (December 18th) I saw him with Dr. Kobike, and found a typical exanthematous eruption, extending all over the body; temperature, 104° F.; pulse, 140; respirations slightly accelerated. The appearance was typical of bronchitis and measles. For the relief of the high temperature and the excessive thirst I gave one dose of fifteen grains of apolysin, followed in an hour by a second—in all thirty grains. He was so much improved that in the evening of the same day, when he had headache again and thirst, he of his own desire took two more of the same powders in the same manner.

Besides a slight diaphoresis following the thirty

grains of apolysin, nothing was complained of by him. The course of his measles and bronchitis was normal, and after five days the temperature became entirely normal and the patient was discharged as cured.

On December 15th his brother, who, at the time of my first visit, was perfectly well and normal, now had a fever, a chill, intense pains in the limbs, sleeplessness, constant headache, thirst, sneezing, coughing, and a disagreeable feeling. The symptoms of measles being so clear, I advised a placebo, and put him to bed, shading his eyes from the strong sunlight and ordering cooling drinks.

On the following day there was intense headache. The temperature, 105° F., later went to 106° F. on the same day, accompanied by muttering delirium, thirst, and an intense eruption which appeared scarlatinous rather than morbillous; there were intense pulmonary congestion and dyspnoea, but no apparent consolidation.

The percussion note and auscultation were normal, the breathing vesicular on one side, with a few râles, sonorous and sibilant, on the other. During the height of the disease, while the temperature was between 105° and 106° F., I gave apolysin without any apparent effect. The dose was fifteen grains. When the temperature was 106° F., I gave thirty grains at one dose, followed by a second dose of thirty grains in an hour. This was followed, as in the previous cases, by a slight reaction, consisting in perspiration, and then the temperature fell from 106° to 101° F. The temperature did not rise beyond 102° F. on the following day, although no apolysin was given. The eruption of measles continued to cover the body, and at the time of writing the patient was still under treatment for a mild bronchitis, there being besides this evidences of the desquamation of the skin consequent to a severe form of measles. He was convalescing, and, beyond liquid diet, received no stimulation whatsoever nor any diaphoretics, which we are sometimes in the habit of giving.

The largest dose of apolysin given by me to an adult has been sixty grains, or four grammes. It is plain, therefore, that enormous doses of this drug may be given with safety, and the tolerance of my patients for this new drug has been surprising; not only does it not influence the heart's action, but I have yet to see a case in which the pulse was either slowed or made worse in character, or in which there has been anything but a slight reaction, consisting of a diaphoresis, with no uncomfortable symptoms whatever. Nor have I ever noticed a symptom of nausea, which is so common, not to speak of the dangerous symptoms of cyanosis, which I have found to accompany the use of all antipyretics heretofore.

It is plain, therefore, that a maximum dose must be a very large one, and I must leave it to the judgment of more competent observers to state what the limit of this drug shall be, for I have given an adult within twelve hours 360 grains, or rather, to be more specific, twelve powders containing two grams each, one powder every hour. In the cases of children, in which we frequently have these high temperatures, followed by convulsions, we are sometimes at a loss to know what to do. In my limited experience I have found that while some children of one year can receive and tolerate five grains of this new drug, other children will tolerate ten or even fifteen grains every two or three hours, the quantity and frequency depending on the urgency of the case and the reduction of the fever, or on the manifestation of some reaction, such as a profuse perspiration all over the body, which has satisfied me to discontinue the drug.

CASE VIII.—G. S.—, five years of age, was seen by me on November 12th. The mother told me the boy had been feverish, very thirsty, slightly consti-

pated, and restless the previous night. The child appeared drowsy and had no appetite. A slight cough was also noticed. A careful examination revealed a few rhonchi scattered through the lungs. The heart was normal. There was no exanthema, but the skin was dry and hot; the liver, spleen, and stomach were as near normal as possible. Some tympanites were manifest, but there was no special tenderness. The child urinated freely; the urine was examined, and but for a slight excess of urates and phosphates showed no abnormality. The eyes appeared normal. The tongue was coated with whitish fur, and the papillæ of the tongue were enlarged. The pharynx and tonsils were very red; no membrane was visible. He had not complained of pain on swallowing; there was no expectoration. Temperature in the rectum was 104° F.; pulse, 146; respiration, 43; no dyspnoea. The child was so obstinate that it required the combined strength of two adults to hold him while forcing his mouth open to inspect his throat. So owing to the obstinacy of my little patient I ordered apolysin in suppositories to be inserted in the rectum, giving the following dose:

R Apolysin..... ʒ ij.
Olei theobromæ..... ʒ ij.
M. ft. suppositor. l. a. No. xij. Sig. Use one suppository every two hours.

It is advisable to have the suppositories cone-shaped and lubricated with glycerin or vaseline before introducing them. Push them gently into the anus and hold the buttocks for a few moments, laying the child over the lap with its face downward. Always put the suppositories in a cool place when not in use, to guard against their melting. In giving this drug per rectum I invariably use double the usual dose per mouth.

To sum up, then, I would formulate the following rule: We may begin to give a child of one year five grains of apolysin, to be repeated every two or three hours, the intervals depending on the urgency for reduction of hyperpyrexia. If there is no distinct effect noticeable from the five-grain dose after three doses, it is perfectly safe to give doses of ten grains each every two hours until the fever has been reduced.

I have also frequently combined apolysin with calomel, and lately have combined it with the compound powder of jalap in the following manner:

R Apolysin..... gr. lx.
Calomel..... gr. vi.
Sacch. alb..... gr. lx.
M. ft. chart. No. xij. Sig. One powder every two hours for a child one year old.

Apolysin is applicable for the reduction of high temperatures in any and all affections in which antipyretics are required.

My best results were obtained by giving the powders before meals, although some authors advise giving them after meals.

To children five grains for the first year and one grain more for each additional year may be given with some sugar every two hours or even hourly until fever has been reduced sufficiently to satisfy the physician of the removal of the liability to convulsions.

With some children it is preferable to give apolysin per rectum, owing to the difficulties of giving them medicines. In giving drugs per rectum I follow the usual rule of doubling the dose per mouth, and give a child one year old ten grains of apolysin in a suppository, as may be required. When using rectal medication I invariably advise the precaution of a cleansing enema of one pint of glycerin, soap water, or castile-soap water injected quite high in the rectum or into the colon.

Not one single case showed disagreeable effects from this drug, and it was very well tolerated by weak

stomachs, such, for example, as those of children who have been brought up on almost a starvation diet, with bad hygienic surroundings, with alcoholic parents, and in some instances in our ordinary tenement houses.

In all thirty-eight cases were experimented with, eight of which I here report. Several are still under treatment and observation. One highly instructive case of double lobar pneumonia occurring in the child of a physician I am not at liberty to report. The one point which was noted in the latter case was the ease with which fever could be reduced, without even the pulse showing any alteration in frequency or rhythm, and without reaction directly attributable to the drug.

In not one single instance did I notice a subnormal temperature. Copious perspiration was frequently found when large doses of apolysin had been taken.

In several cases, notably one, children took ten grains every hour for twelve hours or one hundred and twenty grains in all. I took especial pains to notice that not a single eruption ever followed large doses of apolysin.

R Apolysin,
Sacch. alb..... ʒā gr. lx.
Pulv. jalap. comp..... gr. xxx.
M. ft. chart. No. xij. Sig. One powder every two hours.

For ordinary catarrhal gastritis attended with high fever and with sluggishness of the bowels, I have found that these powders reduced the temperature, besides stimulating peristalsis, and evacuated the infected material from the stomach and bowel.

What I have previously said, however, in regard to washing the stomach by gentle irrigation and flushing the bowel after reducing the temperature, should be well borne in mind.

That this drug can be given with impunity before or after meals I have frequently tested, but it seemed to me that the best results were obtained by giving the drug before meals.

Apolysin can be combined with sodium bicarbonate by giving equal doses of each, and the most convenient plan for giving it has been in the form of tablets containing seven and one-half grains of apolysin and two grains of sodium bicarbonate.

I do not, however, for a moment undervalue the great importance of dietetic treatment in the diseases of children, yet it must be borne in mind that frequently symptomatic treatment has to be instituted when the causes are unknown and the reduction of a high temperature by a drug that is not a cardiac depressant is one of the greatest boons to mankind.

I would repeat the statement made in the beginning of my paper, that in using this drug I have discarded all antipyretics, because I have never seen the reduction of temperature accomplished by any one of them without the system suffering from a general depression caused by weakening of the heart and subsequent derangements.

It is plain from what I have reported in the treatment of a severe form of acute articular rheumatism that apolysin can hold its own in the treatment of acute specific diseases in which quinine and antipyrin have been so often given, without, however, making the body suffer from the consequent heart depression.

It is therefore one of the most valued additions to the materia medica in the treatment of that most dreaded disease, "la grippe."

In infancy it will prove one of the most valuable drugs if given in large doses, and herein lies its safety, because owing to its chemical constitution it has no cumulative effect, as has digitalis for example.

In a case reported by me in this paper I gave 360 grains of apolysin without having the patient suffer any depressed feeling; on the contrary, the more he took of the drug, the brighter and better he felt.

I do not wish to close this paper without giving my

good old friend cold water its proper place in the materia medica, as an additional factor in reducing temperatures, and while I am extremely enthusiastic concerning the brilliant result obtained by me in the treatment of fevers with apolysin, there are instances when a cold bath in addition to the use of apolysin will aid this new drug in the performance of its noble duty.

167 SECOND AVENUE.

INQUIRIES RELATING TO THE COMPARATIVE VALUE OF EXPECTORANTS AND COUGH REMEDIES.¹

By JAMES K. CROOK, M.A., M.D.,

INSTRUCTOR IN CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, ETC.

The following report is based on a series of clinical investigations made by the author during the year 1895 and in 1896 up to January 25th. The object of these inquiries was to test individually and separately, and without reference to the researches of others, a number of the principal therapeutic agents in use at the present day for the relief of cough. In addition the author begs to report his experience with several drugs concerning the value of which in this direction little is so far known. A list of the agents employed, together with the results obtained, is shown in the subjoined table.

As a number of old remedies are included, some of the results are simply corroboratory of what is already known; this fact, however, is no disparagement of their correctness nor can it be said to impair their value as a contribution to our knowledge. The author is well aware of the following important disadvantage in investigating the value of cough medicines, viz., the testimony is almost wholly of a subjective character, i.e., it is based upon information derived from ques-

¹ Read by title before the Medical Society of the State of New York, January 30, 1896.

tioning the persons affected. Objective examinations of the chest are of some value in securing the desired evidence, but we cannot know whether a cough is ameliorated, unimproved, or intensified except from what the patient tells us. This objection, however, holds good through the whole domain of clinical medicine. We have no other means of acquiring a knowledge of the immediate effects of a majority of our internal remedies. It may be said that these investigations were entered into without prejudice or bias, the author having no point to prove, no theory to defend. The remedies were administered in each case for a sufficient length of time to fully estimate their value. If the object sought was obtained—that is, if the cough was made loose and easy or was entirely arrested—the case was noted in the table as “successful.” If the patient improved to a moderate degree the case was indorsed as “partially successful.” If no improvement occurred it was entered as a “failure.” It is probable that the proportion of successful cases is considerably curtailed by the failure of some of the patients to report after recovery. When only moderate success or failure resulted in any given case after sufficient trial, the medicine was changed. For this reason the sum of the tests made is considerably greater than the total number of persons under observation. With a few exceptions unselected cases were used in testing the remedies—the symptom of cough being the only criterion. Each drug was employed in a neutral combination—liquids and soluble solids being given with a little simple syrup and water, while insoluble remedies were prescribed with a few grains of powdered sugar.

We will now proceed to analyze these results, taking the drugs used in their alphabetical order. It may be stated that in summing up his conclusions with certain of these remedies the author holds in mind his experience with them during a period of thirteen years in dispensary and private practice.

Aconite.—This remedy was employed in twelve cases of ordinary unselected bronchial cough. The tincture of the root was chosen and was administered in doses ranging from one to four drops in a drachm of sweetened water every two or three hours. The preparation showed no influence whatever over the symptom of cough, except in one case complicated by, and apparently due to, cardiac hypertrophy, in which some amelioration was expressed by the patient. The drug has apparently no value in the coughs of ordinary bronchitis.

Ammonium Bromide was tested in eighteen cases, with a result of twelve somewhat benefited and six failures. None of them was cured. The expectorant properties of this remedy must be exceedingly slight. It is of no use in the common coughs of bronchitis and phthisis beyond promoting sleep and somewhat allaying bronchial irritation. Its range of application in the treatment of coughs is very limited, although in the author's experience it is more reliable than either the bromide of potassium or of sodium. It was found necessary to give the remedy in doses of not less than ten grains every four hours in order to recognize any benefit from its use.

Ammonium Carbonate.—This salt was tried in forty unselected cases of cough with the following results: Success in ten cases, partial success in fifteen, and failure in fifteen. The carbonate of ammonium is not nearly so good an expectorant as the muriate. Indeed it may well be doubted whether this salt promotes to any appreciable extent the secretion of the broncho-pulmonary mucous membrane. However, it is a powerful cardiac and respiratory stimulant, and is of unquestioned value in certain conditions. In the teasing, distressing coughs of pulmonary congestion due to mitral disease, in the weak and fruitless

coughs of bronchitis in aged persons, in the suffocative catarrhs of infancy, in certain cases of emphysema, and in bronchiectasis attended by dyspnoea, it is a most useful therapeutic agent. It finds its best application in cases attended by weak heart and overtaxed bronchial power from any cause. This drug forms the base of the familiar Stokes' expectorant, but the author is convinced that its proportion in that formula, one grain to one drachm, is insufficient. The remedy will hardly avail in adults in doses of less than three grains, and must usually be increased to five, six, seven, or even ten grains every three or four hours. In cases of acute pneumonia it is better to begin with five-grain doses at once.

Ammonium Chloride.—For the purposes of this inquiry sixty unselected cases of cough were treated with this salt. Of these cases twenty-five are noted as being successful, twenty were partially successful, while failure resulted in fifteen cases. The conclusions are as follows: The muriate of ammonia is a useful stimulating expectorant. It undoubtedly promotes the secretion of the broncho-pulmonary mucous membrane and increases the bronchial muscular power. It is especially valuable in the early stages of bronchitis prior to the appearance of exudation. It is also very useful in the later stages of bronchitis, as well as in phthisis, when the exudation may be either scanty or abundant but is viscid, tenacious, and difficult to dislodge. It is of little or no benefit in the coughs of pleurisy, reflex coughs, or in coughs of any kind attended by loose and free expectoration. It hardly avails to give this remedy in beginning doses of less than three grains once in two, three, or four hours, and it is generally advisable to increase the quantity rapidly to five, ten, or even fifteen grains.

Antimony.—The effects of this preparation were observed in twenty-four cases. The wine was chosen for the tests and administered in doses of five to twenty drops every two, three, or four hours, in a drachm of simple syrup and water. Success was obtained in eight cases, partial success in twelve, and failure resulted in four. This drug is undoubtedly palliative and even curative in some cases of irritative cough, and may be ranked as a powerful nauseant expectorant. Its virtues, however, hardly compensate for its treacherous and toxic character when long continued, and the author believes that it is justly reserved for only occasional use.

Apomorphine.—The hydrochlorate of apomorphine was tried in twenty-two cases. Eight were entirely relieved, twelve partially so, while only two were unimproved. With due care in the administration of this powerful drug, the author believes it to possess exceedingly valuable properties as a cough remedy. It may be ranked as a decided stimulating expectorant of the nauseant group and may be used in conditions where such a remedy is indicated, with certain exceptions. Its use should be limited to adults and especially to those of robust physiques and without cardiac disease or weakness. It was prescribed by the author in doses of one-twenty-fourth of a grain in a drachm of sweetened water. This dose was repeated five times daily at four-hour intervals. It may be carefully increased to one-sixteenth or one-tenth of a grain, but this is seldom necessary or advisable. The solution assumes an emerald-green tinge, probably from oxidation, on standing, and should be freshly prepared as needed. One or two drops of dilute hydrochloric acid to the ounce prevents this coloration, and it is retarded by keeping the solution in a bluish or brownish colored bottle and placing in a dark closet.

Chloroform.—The spirit of chloroform combined with sweetened water was prescribed in twelve cases, in doses ranging from five to twenty drops every two, three, or four hours. These were all unimportant

cases of bronchitis of the larger tubes. Two cases were entirely successful, six partially so, and four received no benefit. The remedy evidently possesses some palliative influence in irritable states of the bronchial mucous membrane. Some of the patients stated that they had a spell of coughing after every dose, due probably to a small quantity of the drug escaping into the larynx when swallowed. This effect can generally be averted by thoroughly shaking the mixture immediately before taking. Chloroform can hardly be called an expectorant remedy and its use may generally be limited to a combination with muriate of ammonia, the disagreeable taste of which it materially modifies.

Codeine.—The sulphate of codeine combined with a little powdered sugar was tested in sixteen cases. The preparations of Merck and of Powers & Weightman were employed, and the doses ranged from one-tenth to one-fourth of a grain every two, three, or four hours. Some relief occurred in every instance, but none of the cases was entirely cured of the cough. It is certainly a valuable remedy in irritative coughs and has a much wider range of application when given in combination with phenacetin (see formula). Constipating effects and the concurrent disadvantage of anorexia were observed in most cases when the dose was carried to one-sixth or one-fourth of a grain. It has some of the drawbacks of the opiate class in general, though not in so marked a degree.

Creosote.—The author presented a paper on this drug to the Post-Graduate Clinical Society of New York in the spring of 1895.¹ His experience with the remedy prior to that time had not been of a very hopeful character. Stimulated by the experience of some of the speakers who discussed the paper, the writer has since prescribed the remedy in much larger doses than before. For the purpose of this inquiry thirty cases, all suffering from phthisis or suspected phthisis, were selected. It was generally prescribed in pill form, beginning with six one-grain pills daily—one before and one after each meal—and rapidly pushed to twenty, thirty, forty, and in some cases sixty grains a day. The favorable effects of the drug could hardly be appreciated before reaching fifteen or twenty grains a day, but it was necessary to begin with the smaller doses in order to establish a tolerance. The largest dose given was sixteen four-grain pills a day. No other remedy was used during the period of administration of the creosote. Regarding the influence of the drug on the symptom of cough, the following facts were noted: In large doses it unquestionably possesses the power to diminish the amount of the expectoration, to improve its character, and to lessen the frequency of the coughing efforts. These effects were noticed in all the cases under observation after the daily dose had reached from twenty to thirty grains. In three cases of suspected phthisis all manifestations of the disease disappeared. Although not enough time has yet elapsed on which to base a positive opinion, it is believed that at least two well-advanced cases of consumption have yielded to large doses. The writer hopes to make his late experience with creosote the basis of a fuller report within a short time.

Glycerin.—This was prescribed in doses of ten to thirty minims combined with water in twelve cases. Some alleviation was observed in five cases, while seven remained unimproved. This substance promotes bronchial secretion somewhat but it has little value as a cough remedy when used alone. Its use should be reserved for combination with alcohol or one of the stronger expectorants.

Glycyrrhiza was examined in twenty cases. The solid extract was employed in one- and two-grain powders with sugar and the fluid extract in doses of

¹ Published in the Post-Graduate for September, 1895.

fifteen to thirty drops in sweetened water. Some improvement in the character of the cough was expressed by the patient in every case. Licorice may be classed as a mild stimulating expectorant and also possesses virtues of a sedative character. It is a useful member of the expectorant family but is hardly to be relied upon except as an adjuvant.

Hoffman's Anodyne.—This can hardly be called a cough medicine proper, and when given alone seems to have no value in the coughs of uncomplicated bronchitis. But in cases accompanied by asthma, emphysema, or painful action of the heart it is a remedy of great value. In making these tests it was employed by the author in five cases having one or more of these complications. A measure of relief was obtained in every case. In five ordinary cases of bronchial cough no improvement occurred. It was administered in doses of ten to thirty minims at intervals of one, two, and three hours.

Hydrocyanic Acid.—This preparation is extensively used in the public hospitals and dispensaries of New York in the form of the "hydrocyanic cough mixture," containing one minim of dilute hydrocyanic acid and one-thirty-second of a grain of the sulphate of morphine to the dose. So far as I know, its virtues have not been tested except in combination. In the last edition of his work on "Materia Medica and Therapeutics," Prof. H. C. Wood states that he has always used hydrocyanic acid in coughs in connection with morphine, so that he does not know exactly what value to attach to it. The author has tested its merits in twenty-four cases of unselected coughs in doses of one to three drops every three or four hours. Some improvement resulted in sixteen cases, while eight were entire failures. None of the cases was entirely cured so far as the writer could learn. In safe doses it may be said that hydrocyanic acid is nothing more than a mild sedative. It lends a pleasant flavor to its combinations but probably adds little to their actual remedial value.

Ipecac.—The syrup of ipecac was employed in thirty cases in doses ranging from five to twenty-five drops every three hours. Five patients reported themselves as being entirely relieved, twenty were somewhat improved, and five received no benefit. This drug evidently possesses remedial value of a high order. It is one of the most reliable and perhaps the safest of the nauseant expectorants, and forms a very desirable addition to cough mixtures.

Opiates.—The author has already referred to apomorphine and codeine, which, although derived from opium, are not usually classed as opiates. In testing agents possessing the physiological actions of this drug paregoric and morphine were selected. The former was used in doses of five to twenty drops with simple syrup and water, and the latter in doses of one-thirty-second to one-tenth of a grain with pulverized sugar or in aqueous solution. These preparations were tried in fifteen unselected cases of cough. This symptom was entirely arrested in three cases, ten were partially relieved, while two were unimproved. In the larger doses mentioned these remedies produced a disagreeable dryness of the mouth and thirst, as well as constipation and loss of appetite. These effects were not noticed in very small doses.

Phenacetin.—So far as the author is aware, this remedy has not hitherto been employed simply as a cough remedy. Its use for such a purpose is not mentioned in any of the recent dispensaries or works on materia medica and therapeutics. It was tested by the writer in thirty unselected cases of bronchial and pulmonary coughs, with the following results: Entire relief occurred in eight cases, some improvement in twenty cases, while failure resulted in two cases. The dose given was from one to three grains every two, three,

or four hours, combined with ten grains of pulverized white sugar. Phenacetin was found to be an exceedingly valuable and efficacious remedy. Good effects were produced in many cases in which all other remedies had failed. It is not an expectorant, but on the other hand it has no tendency to render the mucous membrane of the respiratory tract dry and irritable. Its best effects are seen in cases where the frequency of the cough is disproportionate to the amount of expectoration. It is almost a specific in the early stages of bronchitis, but its application may be extended to well-nigh the entire range of irritable coughs. The action of the remedy is probably that of a sedative to the sensory nerve endings in the broncho-pulmonary structures. In allaying coughs due to hyper-excitability of the respiratory tract the writer believes phenacetin to be the best single remedy we have at hand. In the form used in these tests it is entirely unobjectionable to the palate and is well borne by the most delicate stomach. The only disagreeable effects observed from its use were the occurrence of frequent sweats in some cases, which, however, were probably not harmful. Phenacetin acts exceedingly well in combination with licorice and codeine (see formula).

Potassium Bromide and its congener, the sodium bromide, were tested in ten cases of ordinary bronchial coughs. No relief was observed in any case, although in several instances the drugs were given in doses as high as twenty grains four times a day. The author is well aware from past experience that the bromides are sometimes efficacious in certain cases of obscure reflex cough, due to ovarian, uterine, or spinal irritation; but they are little better than useless in pure broncho-pulmonary coughs.

Potassium Iodide was tested in thirty-seven cases in doses of five to twenty grains four times a day. The remedy was somewhat beneficial in sixteen cases and failed absolutely in twenty-one. The conclusions reached from this analysis sustain those formed by the author as a result of many years' experience with this agent. It is useless in the coughs of acute phthisis, bronchitis, or tracheitis. The salt has no expectorant properties worth mentioning. It is somewhat useful in cases of chronic bronchitis, especially in those complicated by asthma, emphysema, and bronchial dilations, and its use should be limited to such cases. The remedy probably tends to promote the removal of exudation by absorption.

Squill.—The simple syrup of squill was tried in twenty cases in doses of ten to thirty drops every three or four hours. It produced some relief from the cough in ten cases, while in ten others no benefit was appreciable. The remedy evidently possesses some virtue as a mild stimulating expectorant but has little positive value when given alone. As the syrup contains acetic acid it cannot be given with the carbonate of ammonium.

Sodium Chloride was used tentatively in twelve cases of mild bronchial and tracheal cough. Eight cases reported benefit from its use, while four were unimproved. It was administered in sweetened water in doses of five to twenty grains four times a day. In the latter doses it caused slight nausea in several instances, but was about as pleasant as the muriate of ammonium when given in the same way. Common salt seems to stimulate bronchial secretion somewhat but it cannot rank with ammonium chloride in expectorant properties.

Terebene was employed in twenty cases in doses of five to ten drops on sugar every four hours. It has been said that this mixture forms an insoluble and indigestible mass, but the author has seen no reason after seven or eight years' use to be dissatisfied with it. Two cases reported complete relief, fourteen partial relief, and four no improvement. The preparation is

comparatively useless in acute bronchitis. Its best effects are seen in chronic bronchial troubles, including fetid bronchitis and bronchiectasis, and in advanced phthisis. It seems to promote bronchial secretion to a moderate degree, improves the character of the expectoration, and diminishes the frequency of the cough.

Terpin Hydrate was tested in fifteen cases in doses ranging from two to four grains (three grains being the average quantity) four to six times a day. It seemed to produce some relief in three cases, while in twelve no benefit whatever was perceptible. No expectorant effects were observed in any case. The author's observations lead him to the conclusion that terpin hydrate may be safely excluded from the list of cough remedies.

Tolu.—The syrup of tolu was used experimentally in fifteen cases in doses of twenty drops to one drachm. Two cases were successful, ten partially successful, while three were failures. Tolu is a mild, stimulating expectorant. In addition to its intrinsic value, the grateful taste of the syrup makes it a most valuable vehicle for the administration of more powerful remedies.

Wild Cherry.—The syrup of wild cherry was tested in ten cases in doses of one-half to one drachm every three or four hours. Four cases were benefited by it, while six received no improvement. It is the opinion of the author that wild-cherry syrup possesses less value as a cough remedy than the syrup of tolu, although it has some compensatory virtues as a tonic. In broncho-pulmonary therapeutics it may be regarded simply as a vehicle of occasional service in the administration of other cough medicines.

The author lays no claim to originality in the observation that few cough remedies possess any great value when given alone. The best results are achieved by a scientific combination of two or more remedies, having due regard for their chemical compatibility, their physiological actions, and their applicability in individual cases. The following formulas have been thoroughly tested by the writer in hospital and private practice, and may be trusted to render good service in properly selected cases:

1. For irritative coughs:

R Phenacetin..... gr. xx.-xl.
Ext. glycyrrhizæ..... gr. xx.
Sacch. albi..... ʒ ij.

Fiat pulvis, in chartulas xx. dividendus. S. One to be taken at one, two, or three hour intervals.

2. For same of more obstinate character:

R Phenacetin..... gr. i.
Ext. glycyrrhizæ..... gr. xx.
Codeinæ sulphatis..... gr. ij.-gr. iv.
Sacch. albi..... ʒ ij.

Fiat pulvis, in chartulas xx. dividendus. S. One to be taken every two, three, or four hours.

3. When an expectorant effect is desired:

R Extracti glycyrrhizæ..... gr. xx.
Phenacetin..... gr. xx.-xl.
Ammonii muriatis..... ʒ i.-ij.
Sacch. albi..... ʒ ij.

M. et in chart. xx. div. S. One powder to be taken in a little water every two, three, or four hours.

4. A good stimulating expectorant for adults:

R Apomorph. hydrochloratis..... gr. i.
Syr. ipecacuanhæ..... fl. ʒ ij.
Syr. tolutani..... fl. ʒ i.
Aque dest..... q.s. ad fl. ʒ iiij.

Ft. mist. S. A teaspoonful five times daily at four-hour intervals. Shake well before using. Prepare freshly as required and keep in a dark-colored bottle.

5. A good stimulating expectorant for every-day bronchial and phthisical coughs:

R Ammonii muriatis..... ʒ ij.
Tincturæ opii camphoratæ,
Spiritus chloroformi,
Syr. ipecacuanhæ..... āā fl. ʒ ij.
Syr. prun. virginianæ..... q.s. ad fl. ʒ iiij.

M. S. A teaspoonful every three or four hours. Shake well before using.

6. For weak and fruitless coughs with loss of bronchial power:

R Ammon. carbonatis..... ʒ i.-ij.
Tinct. tolutani..... fl. ʒ ij.
Syr. senegæ,
Spiritus vini gallici,
Syr. simplicis..... āā fl. ʒ iv.
Aque destillatæ..... q.s. ad fl. ʒ iiij.

Ft. mist. S. A teaspoonful in a little water every two, three, or four hours.

7. For asthmatic and emphysematous coughs:

R Spiritus ætheris compositi..... fl. ʒ iv.
Potassii iodidi,
Ammon. muriatis..... āā ʒ ij.
Codeinæ sulphatis..... gr. ij.
Syr. tolutani..... fl. ʒ iv.
Aque des..... q.s. ad fl. ʒ iiij.

M. S. A teaspoonful every two, three, or four hours.

8. For recurring bronchitis or winter cough:

R Terebene..... fl. ʒ vi.
Ol. eucalypti..... fl. ʒ ij.

M. S. Ten to fifteen drops on a little sugar every three, or four hours.

In conclusion the author begs to state that his studies relating to cough remedies are still in progress, and he hopes within a few months to present a further report which will include some clinical observations on a number of recently prepared expectorant preparations.

36 EAST TWENTY-NINTH STREET, NEW YORK.

SOME POSTURAL EXPEDIENTS IN OBSTETRICS AND MEDICINE.

By THOMAS R. EVANS, M.D.,

MT. CARBON, W. VA.

THIS paper is not put forward as one of unusual originality but is offered to recall a few old methods of treatment, some of which seem to have been forgotten and others to be unknown in certain quarters.

There are many deaths from asphyxia neonatorum because of the neglect to carry out the old injunction to "lay them on their right side because it is right." This wise and obvious precaution was taught seventy-five years ago in Philadelphia, then the Athens of the obstetric science. But so far as I know it is not now either taught in the schools or mentioned in our otherwise excellent books. By such posture the valve of the foramen ovale, which valve is not mentioned in my edition of Gray's "Anatomy," is closed by gravitation, thereby materially assisting hydrostatic pressure in preventing a continuance of antenatal circulation.

Posture could have but little if any effect upon a patent ductus arteriosus, but if respiration is once established the function of the duct ceases. At birth its calibre is much diminished, while that of the pulmonary arteries is much increased. Just before the duct reaches the aorta it springs from the junction of the pulmonary arteries. The chances are doubled and then a thousandfold multiplied that the venous blood will be pumped and aspirated at right angles into the empty vessels of the lungs and not thrown against and into the full and powerful aortic current by the duct. Fluids always flow into the channels of least resistance. By remembering the right-side posture the many needless and fussy details enjoined in the circumstances can be dispensed with, some of which details seem curious.

In one case after the usual methods had been un-

successfully tried for ten minutes, without design but fortunately, the child was placed upon its right side, and "rhythmical traction made on its tongue." "Hardly half a minute elapsed after beginning the traction before the child gave an inspiration" and was safe. The tongue is often an instrument of abuse and is itself sometimes abused. Has it ever been proved that by pulling on it the epiglottis is lifted?

Analogous in work over children in danger from death from an open foramen ovale was the work with patients narcotized with opium. This is given on faith—that so far as physical methods are necessary to the restoration of a patient under opium, it is said that an occasional whisper in his ear will suffice.

A late writer elaborated the theory that by inversion in cases of suspended animation in the new-born the vital flame may be rekindled. Almost any position is safer for the new-born than the dorsal. Inversion in the pale form of asphyxia is physiological, for it compels the liver to give up some of its superabundant and purest blood to the brain. Asphyxia may come on a baby while lying on its back two or three days after birth, as has been shown by Dr. J. D. Bissell, and it may prove fatal unless its position is changed.

The symptoms in this case were the classical ones of cyanosis neonatorum. Between the times of inversion the child was several times placed in the horizontal position, presumably upon its back; the respiration was so embarrassed that the horizontal position was abandoned for six hours, and the infant was saved.

Stertor from apoplexy and in other conditions is diminished, if not stopped, by turning the person on his side.

In constipation defecation is much facilitated by the assumption of the canine attitude in the same act. Dogs are usually constipated, and sometimes are subject to itching but not to bleeding piles. The upright or but slightly prone attitude of civilized man in the act of defecation greatly aggravates if it does not cause certain rectal diseases. The ease of defecation in the attitude approaching that of the four-legged is another of the many points in Darwinism.

Had not obstetrical postures been nationalized women would have somewhat briefer labors and the perineum would be less often injured. Woman is the only animal ever made to give birth upon the back. But for the bugbear of perineal rupture the obstetrical chair of the ancients would be a sensible convenience.

In so-called adherent placenta, when the patient has rested and is not in danger of syncope, to make her sit upon a bidet and bring her powers into play is frequently to cause the expulsion of the placenta, without the pain and maybe the injury of the Credé method and without the danger of infection from the hand in the old method.

Elevation of the hips in enuresis is well known.

Dr. Hunter McGuire told the writer that the next time a case was presented to him for tracheotomy for a foreign body he would first try the relaxing effect of chloroform together with inversion. This seems hopeful, for often after the patient is chloroformed and the incision is made he coughs because of the slight irritation of the atmosphere admitted through the incision, and the foreign body lodges in the mouth. I have never seen ether given before tracheotomy, but it lacks the element of the great relaxation caused by chloroform and is otherwise unsuited, if not contraindicated for the trial of this experiment. In the case of a cockle-burr or a vulnerating body ether might render matters worse by provoking excessive cough and the guidance of the patient's sensibilities would be lost.

Creosote by the Rectum.—Use in suppositories only diluted creosote.—KUGLER.

PERMANGANATE OF POTASSIUM IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

By H. B. GARNER, M.D., AND J. B. LEESON, M.D.,
TRAVERSE CITY, MICH.

DURING the past five months we have employed this drug with most gratifying results in five cases of pulmonary tuberculosis.

In July, 1895, we commenced treating Mrs. R—, a phthisical woman, thirty-five years of age; she had a troublesome cough with free expectoration and a constant temperature ranging from 100° to 103° F. The sputum was loaded with tubercle bacilli and she was so reduced in health and strength that only with difficulty could she get from the depot to our office, a distance of fifteen rods.

We put her on the cod-liver oil and creosote treatment for several days, but no improvement could be observed. The patient continued very weak and feverish, coughing and perspiring freely at night. During the latter part of July we put her on one-grain doses of permanganate of potassium before breakfast, tablespoonful of wine of cod-liver oil one hour after meals, and ten grains of salicylic acid before retiring.

For the first two days the drug caused nausea and vomiting, but after that it was readily tolerated and within eight days marked improvement was observed. The patient has now made a perfect recovery, is free from cough, expectoration, and fever, and weighs more than she has before in ten years.

In September Mr. B—, a phthisical man of thirty-seven years of age, came to us for treatment. In making a careful examination we found that he had a cavity in the left lung, constant cough, temperature 103° F., and he complained of feeling chilly. He was much emaciated and so weak that he got about with great difficulty. We put him on the potassium-permanganate treatment and within four days the patient began to improve, and at the end of three weeks he had only occasional fever and coughed but little. Five weeks after his first call at our office he was able to go to work and felt stronger than he had for months. Unfortunately this patient moved away from the city and we have lost sight of him.

The 1st of August Mr. M—, nineteen years of age, came to our office for consultation. Upon thorough examination we found dulness at the right apex, respirations shallow and 35 per minute, temperature 102° F., pulse 100 per minute; he was much debilitated, had been having night sweats for a month, and had marked anorexia. We put him on the permanganate of potassium treatment and were much pleased to observe a marked improvement within five days. This patient continued to improve rapidly and at the end of six weeks had made a perfect recovery.

Six weeks ago Mr. L—, a foreigner of forty-five years of age, consulted us relative to his condition. He stated that he had been treated for nearly a year but that he was steadily growing weaker. He complained of feeling chilly in the morning, and we found that he had a constant temperature ranging from 100° to 103° F., marked anorexia, and a constant cough with free, glairy expectoration.

He was much emaciated and very pallid in appearance. We put him on the permanganate of potassium treatment and at the expiration of four days observed improvement; two weeks from the time he commenced treatment his appetite was good, his temperature normal, and he was gaining rapidly in flesh. At present he appears perfectly recovered and has resumed his work.

Dr. Z. H. Evans kindly reports the following case:

"Mrs. H—, a married woman of twenty-seven years of age and the mother of three children, the old-

est of whom is three years, was taken ill in April, 1895. She was suffering from irritability of the stomach, severe diarrhea, marked tenderness of the abdomen, and had constant fever, slight in the morning and varying from 101° to 102° F. in the evening.

"She had marked anasarca and anorexia, was frightfully emaciated, and was discharging from the bowels from a tablespoonful to six ounces of pus and mucus every two hours. She informed me that her maternal grandmother died with pulmonary tuberculosis and that an aunt on her mother's side had died with scirrhous cancer of the breast. This patient had enlargement of cervical and inguinal glands.

"I diagnosed tubercular peritonitis complicated with intestinal tuberculosis and advised an operation, but the patient would not consent to this. I then put the patient on elaterium, calomel, and jalap; these drugs were followed by cod-liver oil, quinine, and iron.

"The patient went from bad to worse, gradually failing every day, and there was nothing to be hoped from the above treatment. Some four weeks ago I was informed by Dr. H. B. Garner of the use of the permanganate of potassium and salicylic acid in the treatment of pulmonary tuberculosis. I at once put this patient on the potassium treatment and was pleased to observe immediate results. The discharges from the bowels commenced to lessen, both in frequency and in amount.

"After the first week there was absence of fever, increase in flesh, and marked improvement in appetite.

"The patient continued to gain steadily, has now fully recovered, and has resumed charge of household duties."

Dr. C. A. Clark, of Williamsburg, Mich., reports the following case:

"Mrs. B—, aged fifty-six, married, mother of six children; family history good. She contracted pulmonary tuberculosis thirteen months ago and has been confined to her bed more or less ever since, unable to do any kind of work. She has had constant cough with free, glairy expectoration loaded with tubercle bacilli, constant temperature ranging from 101° to 104° F., night sweats continuously, anorexia, debility, and emaciation. I used creosote, cod-liver oil and maltine, and every other remedy that I had heard of or seen recommended, but without success, as the patient kept going from bad to worse. Her cough became so distressing that she could not sleep at night; her appetite was entirely gone. I was at my wits' end to know what to do, as I had failed to give my patient any relief and saw her gradually dying before my eyes.

"In conversation with Dr. H. B. Garner about six weeks ago concerning the case, he told me of the success that he and Dr. Leeson had had in the treatment of tuberculosis with the permanganate of potassium and salicylic acid. I determined to try it and forthwith placed her on two grains of permanganate of potassium before breakfast, cod-liver oil after meals, and ten grains of salicylic acid before retiring, with the following result:

"In three days the patient began to feel better, cough was not so troublesome, and appetite was better; in two weeks she had no fever, no night sweats, and expectoration had ceased. She had slight cough, but ate well and had begun to gain in weight. At the expiration of six weeks she was stronger than she had been for five years.

"She says she never felt better in her life, sleeps well every night, has no cough, and weighs ten pounds more than she did a month ago. I still have her on this treatment but have ceased to visit her, as I consider her entirely cured."

At the present time we have several cases on the potassium permanganate and salicylic-acid treatment, all of which are doing well.

Progress of Medical Science.

Camphor for Ether Collapse.—Schilling affirms that hypodermic injections of camphor in larger doses than the text-books advise are beneficial in ether collapse. Half-grain doses are very effective, but the results obtained from one-grain doses are extremely gratifying. The solution should be one part camphor to ten parts olive oil. As the camphor is eliminated within two hours it has no cumulative effect.—*Münch. med. Woch.*

For Sickness Following the Administration of Chloroform.—Lewin finds that a linen cloth steeped in vinegar placed over the face of the patient and allowed to remain for at least three hours will prevent the sickness following the administration of chloroform.—*Rev. de Chir.*, September, 1895.

Serum Therapy.—Schaefer after considerable research discusses this subject, with the following general results: 1. Tuberculosis. Treated with serum obtained from refractory animals by Richet and Héricourt without definite results up to present time. 2. Rabies. Immunization by vaccination gives better results than serum treatment. 3. Pneumonia. Serum from immunized rabbits is difficult to obtain, consequently this treatment has not been used to any great extent. The subject is promising enough to deserve further investigation. 4. Enteric fever. Good results have not been obtained in practice, though laboratory experiments are very promising. This may be due to mixed infections or to length of time between the penetration of poison and the treatment. 5. Typhus. Legrain during an epidemic in Algeria used the serum from patients who had suffered from this disease, with good results. 6. Cholera. Cholera in man is different from that in animals. Nothing definite is known as yet, but Behring announces that he has a curative serum. His researches are not yet published. 7. Syphilis. Sometimes good results have been effected with the serum from dogs and lambs. 8. Streptococcus infection. The serum from animals immunized by vaccination has been employed with good effect in angina, erysipelas, and puerperal fever. 9. Cancer. There are no satisfactory results thus far. 10. Tetanus. This affection is very hard to cure in animals and no conclusive results have been obtained in man. The serum, however, acts as a prophylactic agent against tetanus. 11. Diphtheria. Here it is that the serum treatment has scored its most remarkable triumph. The few accidents that have occurred may be overlooked when we consider the wonderful success that has been attained. Serum treatment has also proved useful in snake bites and it may have a brilliant future.—*Arch. Gén. de Méd.*, August, 1895.

Treatment of Alcoholism by Strychnine Nitrate.—Dr. Breed thinks that we have in nitrate of strychnine a remedy for alcoholism that is safer and at the same time gives as good results as the gold cure, Keeley cure, silver-ash cure, etc. It is a treatment that is no secret and can be used by the profession generally. This drug removes the desire for alcoholic stimulation for, as yet, an undetermined length of time without the least effort on the part of the patient; though of course it cannot oblige a man to abstain if he is determined to continue the use of alcohol. Nitrate of strychnine removes the distress and gnawing at the epigastrium so common upon the withdrawal of alcohol; it tones up the nervous system and allays tremulousness and uncertainty of voluntary motions; it restores the appetite and general physical vigor and is incidentally a good heart tonic. These

latter effects restore hope and self-confidence in the patient, and these in turn aid much in his recovery. —*Med. News.*

Strangulated Hernia.—William Burton De Garmo draws the following conclusions from a study of thirty-nine cases of strangulated hernia: (1) Prompt operation saves complications and life and is neither difficult nor dangerous. (2) Medicines, external applications, and rough handling are dangerous. (3) Morphine masks symptoms but does not stop destructive changes. (4) Hot water saves resection or gives prompt evidence of its necessity. (5) Local symptoms are misleading. (6) Operate on a hernia that has been acutely strangulated for twenty-four hours. (7) In every instance open to the internal ring, and always draw the bowel down far enough to examine the actual point of constriction. (8) Infants seldom require operation. (9) It is not advisable to give cathartics after strangulation and the return of a suspicious bowel. —*Annals of Surgery*, April, 1895.

Cervico-Facial Actinomycosis.—M. Meunier recognizes three periods of this disease: the first characterized by tumefaction and a compact induration of an inflammatory appearance; the second by actinomycotic lesions having the appearance of fungus tumors made up of a large number of miliary abscesses, which give rise to the formation of fistulous tracts; the third by marked cachexia and an encroachment upon the bones of the face. Actinomycosis must be distinguished from exterior lesions produced by dental caries, from adenophlegmonous suppurating periostitis, tuberculous cervical glands, syphilitic lesions, malignant tumors, woody phlegmon, etc. One must search in the pus for yellowish granules from one-quarter to one millimetre in diameter; these granules contain the actinomyces or ray fungus. The author has obtained good results by treating actinomycosis with iodide of potassium, which is unfavorable to the viability of the specific fungus. The duration of treatment varies from six weeks to two months. —*Semaine Médicale*, July 17, 1895.

Sterility.—Graefe gives the following causes of sterility: 1. Anomalies of the hymen or malformations of the genital tract. A very large vagina can also be a cause of sterility, as the sperma flows out immediately after coitus. 2. Vaginismus. 3. Excessive acid reaction of the vaginal mucus, which destroys the power of motion in the spermatozoa. 4. Narrow external or internal os, antelexion, retroflexion, endometritis, gonorrhœa, especially with involvement of the adnexa, neoplasms. 5. Constitutional diseases, as tuberculosis, syphilis, chlorosis, and obesity. —*Centralblatt für Gynäk.*, No. 49, 1895.

The Oyster Shuckers' Eye Disease.—Oyster shuckers' keratitis is defined by Dr. Randolph in *The Johns Hopkins Hospital Bulletin* as a traumatic keratitis, where the injury is produced by a particle of shell striking the corner of the eye, and imbedding itself in that organ. The extent of the injury does not explain the violent reaction which follows. Baltimore is the greatest oyster market in the country, and the tenth census of the United States shows that there are at least six thousand shuckers in Maryland, most of them being in the shucking-houses of Baltimore. In many of the Northern cities, including New York, Boston, and Portland, oysters are received in great quantities that have been shucked in that city, so that oyster shucking in the north does not exist as a trade to the same extent as in Baltimore. The magnitude of the oyster industry may be said to account for the frequency of the oyster shucker's keratitis there. The reports of the eye hospitals in Balti-

more contain the records of several hundred cases during the last few years, and during the last several months twenty-four cases have been treated at the Baltimore Presbyterian Eye and Ear Hospital.

Friction with Salt for Urticaria.—Dr. Meynet advocates the following simple measure as very effective in allaying the itching that results from urticarial lesions. Moisten the wheals with cold water and rub with kitchen salt for ten or fifteen seconds. A slight burning followed by a pleasant sensation of coolness is felt; then the itching decreases or ceases entirely and the papules usually disappear. Zinc ointment or rice or almond powder may then be applied. When the urticaria is extensive different parts may be treated successively in order to avoid too great irritation. This need not interfere with other treatment, such as dieting, or a purgative if the urticaria be of toxic origin. Lukewarm baths may prove beneficial. —*Revue de Médecine et de Chirurgie.*

Cutaneous Continuity Restored by Epithelial Grafting.—Mangolt offers the following new method of skin grafting. Let a portion of the body, preferably the inner or outer surface of the forearm, be shaved and disinfected; then make the skin tense and scrape carefully down to the papillary layer with a sharp razor held at right angles to the surface. The blood and epithelium thus removed are transferred to the wound which has been prepared to receive it. Slight pressure and a protective dressing complete the operation. A graft thus applied shows signs of its presence in the course of a week and in three weeks' time a new layer of epithelium usually forms. —*Deutsche medicinische Wochenschrift*, 1895, No. 48.

Dilatation of the Uterus not a Conservative Operation.—Dr. Fournel not only condemns "mutilating" operations, such as removal of the uterine appendages, without due deliberation, but maintains that dilatation of the uterus is in no sense conservative. In mild cases of perimetritis with little or no pain, according to comments made on his observations by the *British Medical Journal*, dilatation has merely a negative effect and deludes the operator, who fancies that it is the cause of ultimate recovery. In very severe and acute cases nobody thinks of dilatation. In cases of distinct suppuration, surgical—that is, truly surgical—treatment is demanded at once. Expectant treatment in these instances is unsurgical, dilatation even more so. Dilatation itself often involves sterility, not rarely death, and very frequently aggravation of the perimetric inflammation which it is supposed to cure. Diagnosis of perimetritis is by no means easy, while experience abundantly proves that very bad cases recover without loss of function. True surgery teaches us to preserve all that can be preserved. The whole of the internal organs must be saved if possible. If not, fecundity must be preserved; in other words, we must not be over dogmatic about removing the appendages on both sides. Should the case be desperate, the hopelessly diseased structures, and nothing besides, must be removed in order to preserve life and health.

Influence of High Altitudes on the Blood.—Drs. Gebhard, Fraenkel, and Grawitz have shown that there is a notable increase in the proportion of the number of corpuscles in the blood in persons who go from a low to a high altitude. This increase takes place in from twenty-four to thirty-six hours. It is possible that this fact may be one of the reasons for the beneficial effects of high altitude in cases of pulmonary tuberculosis. The increase in the red corpuscles is attributed to the desiccating effects of a high atmosphere. —*Modern Medicine.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 22, 1896.

VALUE OF FAMILY HISTORY AND PERSONAL CONDITION IN ESTIMATING A LIABILITY TO CONSUMPTION.¹

WHEN Garibaldi first came to England there was some talk of his marrying a wealthy widow devoted to his cause; objection was made that he had a wife already. "Oh," said Beresford Hope, "we'll get Gladstone to explain her away."

As we know, anything may be proved or explained away by statistics: some one has said they don't even lie truthfully. If the reader has any preconceived ideas, founded on scientific or clinical observation, on family history as a predisposing cause to phthisis, we advise him, especially if he happens to be an examiner for a life insurance company, in justice to the applicant who may come before him, to pass over this contribution.

We say this in all seriousness, for from a long experience we are convinced that the applicant for insurance is not given half a chance. It is a very serious matter for a person to be declined for life insurance, but in nine cases out of ten it is the company who receives the consideration.

This, speaking broadly, is right, but too many life-insurance examiners, especially in the provinces, see only through the eyes of the "medical department"; they are abject subjects of the "divinity which hedges the medical director," hundreds, perhaps thousands, of miles away, and great injustice is done in very many cases. It is the writer's sincere conviction, founded upon a personal experience with medical examiners for our three great companies all over Europe and America, that they have little or no latitude given them; they are little enough encouraged to take a broad view of their duties, Heaven knows, and it is absolutely wrong to send out such a misleading report as the one before us. The examined as well as the company have rights. Some one said, "God is good, and the devil isn't bad, either." The companies might remember this in dealing with those unfortunate applicants who are supposed to be tainted with phthisis.

In the report before us, the tables are made up from figures taken in an extraordinary way (see page 4).

¹The material used for this report consists of

¹ Report to the president of the Mutual Life Insurance Company, by E. G. Marsh, M.D., Medical Director.

22,085 cases, being the entire mortality during the fifteen years from 1879 to 1893. . . . From this material all the cases were selected which gave any record of consumption in the family. The number of such cases was 1,994. A class of cases with 'tainted record' was thus made. . . . The class thus separated might be compared with the 'total remaining,' but for satisfactory reasons it is preferable to employ only an approximately equal number of cases. This has been done by taking all the deaths which occurred in the beginning, middle, or end of the whole period, namely, 1879, 1886, and *part*¹ of 1893, amounting to 2,706 cases."

Why the cases occurring in 1879, 1886, and part of 1893 should be taken, any more than those of any other two years and part of a third, we fail to understand. Why 2,706 rather than 2,101 or 1,200, which is as approximately near 1,994 as is 2,706 or, indeed, any other number, may we ask?

We know that the death rate in the great companies varies very little from year to year, but there is absolutely no ground for supposing that the number of persons dying of phthisis, to wit, 333 (see Table I., page 5 of report), in this series of 2,706 untainted people should not be greatly increased or diminished in the same number of untainted cases arbitrarily selected from any other two years and part of a third.

In other words, there is no reason why these figures should have been taken and less why they should have been used as a basis of comparison.

However, as these figures have been selected as a basis of comparison, let us see what the conclusions are which are drawn from them.

Table No. 3, page 10, shows "the proportionate mortality from consumption and other causes among those with tainted record and arranged according to degree of taint and age at insurance."

Here Dr. Marsh's statistics show that where the father had died of phthisis the percentage of death from the same was 20.7, but where the mother had died it was 15.5; and that this percentage was greater for all ages up to fifty and over, except for the years of life between thirty and thirty-nine, when it was practically the same. These conclusions are absolutely contradicted by scientific facts and medical experience.

It is known that tuberculosis in the father is of infinitely less importance than in the mother. Osler² says in this connection: "There is no evidence that a tuberculous father can directly transmit the disease and experimental evidence is also negative." On the other hand, "We know that maternal is much more common than paternal inheritance." Furthermore, Dr. Marsh has no proof that those who did die of tuberculosis inherited it from the father or mother. Dr. Hilton Fagge very justly remarks, "It is impossible to draw the line between hereditary and accidental tuberculosis." All of which goes to invalidate this conclusion.

In six generations, from 1783 to 1887, the transmission is almost constant through the mother.

¹ The italics are ours.

² "Practice of Medicine," Second Edition, New York, 1895.

Another deduction from Table 3: "On one point, however, the evidence is *conclusive* [the italics are ours], namely, that the death of a brother or a sister is of equal significance with that of a parent."

Practical experience also teaches us that this conclusion is as far from fact as possible. The death of a brother or sister does not prove a necessary predisposition if the parents are healthy. Where it does happen it is probably accidental, and in former years, more especially before the infection of tuberculosis was recognized, was caused by the intimate relation and constant association of one sick child with others in the same family; a condition of things which is happily becoming less every year.

We cannot show more clearly the utter falsity of the conclusions drawn from such statistics as these than to quote—it needs no comment—the conclusion on page 12, to wit: "The subdivision showing a record of 'a parent and brother or sister dead of phthisis,' gives the very smallest percentage of consumption of any class with tainted family record, equal in fact to the general class with no taint."

There is a saving clause in the text *à propos* of this, however, to the effect that "the number of cases in this subdivision is not large, . . . but I believe that special care in selection . . . has had a decided influence in effecting favorable results." If nothing else could bring about such figures, then why draw any conclusions from them?

From the figures of Table 2 "it would appear that the importance which has been attached to a family record of consumption is not modified by the age of the applicant," etc. This is a statement made also by the Equitable Life. But here again the want of anything like a complete family history in a life-insurance paper tends to invalidate this conclusion.

It is not, after all, the age of the applicant at the time of insurance on which we should base his predisposition, but, leaving out the question of weight, his age at the time of his mother's illness and death from phthisis; and in rare instances on his age at the time of his father's illness and death; as, for instance, when there is a distinct and constant taint on the father's side.

We have quoted at length from this report, for it seems to us it is a very serious matter to send out such misleading and unscientific work on such an important and vital subject as tuberculosis.

We hate to think of the gross injustice that will be done and the suffering inflicted on widows and orphans where the bread winner has been "turned down," because of a partial or strict adherence to such utterly false conclusions.

Apart from these particular statistics we very much question the worth of any statistics as to the comparative mortality of tuberculosis or the value of family history in estimating a liability to phthisis, drawn from life insurance examination papers. In the first place, any man of experience as an examiner for life insurance knows how very many persons are ignorant, really or with malice, of the cause of death of parents and brothers or sisters, and that a history of phthisis, more than of any other disease, is denied. And this is

done with impunity in the majority of instances, for it is rarely possible to see the death certificates.

In the writer's experience it is the one thing which many men will lie about; they know or fear it may mean rejection. And so we have the cause of a death really due to consumption put down as due to pneumonia in the majority of instances, and to Heaven knows what else in others.

Furthermore, many cases of incipient phthisis are to-day recognized early and by proper treatment cured, which, up to a few years ago and certainly much later than the year 1878, with which year the cases in the report begin, would have gone on to premature death.

Again, in a life insurance paper the simple statement is made, "died of consumption." Whether it is acute tuberculosis of the lung or fibroid phthisis, a very different thing; whether inherited or accidental, as a wife being infected from a husband, a husband from a wife, a sister from constant nursing of one of the family, etc., and a thousand and one other considerations, is not stated, all of which goes to invalidate any conclusions which may be drawn from the answers made in a life insurance paper.

Finally, with reference to the paper before us, the conclusion in the latter part of the same, that "persons who are under the standard or average of weight are much more liable to consumption than those above this standard," is more in keeping with acknowledged facts, but this fact was so well known that it did not need these statistics to confirm it.

We can only hope, in justice to those who most need assurance, that the medical examiner of the Mutual Life or of any other company will not heed any of the conclusions of this report; they are, as we have said, false, misleading, unscientific.

We are told not to put our faith in princes; there were no statistics in those days.

TYPHOID FEVER IN THE DISTRICT OF COLUMBIA.

THIS extremely important contribution is the result of a special investigation by Dr. George M. Kober. The well-known fact that for many years malarial diseases and typhoid were extremely prevalent in Washington is greatly emphasized in the report before us. It shows conclusively that typhoid fever has increased with approximate uniformity in the District of Columbia during the past twelve years. Five hundred cases distributed over different parts of the city were investigated, and the important fact was developed that the disease is more prevalent in the suburbs and in the northeast, in proportion to the population, than in any other part of the city. In seeking to account for the cause of the fever in the suburbs of Washington we find that 115 cases occurred in 110 houses supplied with methods for the disposal of the excreta as follows: Water closet in house or yard, 18; water closet connected with cesspool, 2; box privies, 86; surface privies, 3; no privy, 1.

Of the 115 cases, 92 were consumers of well water, 18 of Potomac water, 4 of cistern water, and 1 of

spring water. Dr. Kober says that what is true of the suburbs now was, under like circumstances, true of other parts of this city in earlier years; that, before the existence of sewers in the district, there were box privies, many of which are still in use even when leaky or full to overflowing, and before the era of box privies there were sinks and cesspools, all of which would go to account for the soil pollution and constant large mortality from typhoid which has existed for so many years in Washington and which has naturally increased as the city grew. Soil pollution and contaminated water, the doctor says, are the most potent factors in the cause of this disease in the suburbs of Washington.

This report also deals with the city of Washington itself, and the typhoid fever is found to be pretty equally distributed except in the northwest, the best part of the city. The report devotes much space to the relation between the water of the Potomac and the prevalence of typhoid fever in the district, and in this connection Dr. Kober says: "While the Potomac water compares very favorably as regards purity with that of other rivers, there is much reason for believing that it is not at all times free from danger," and quotes Dr. Billings as saying that "at certain times of the year the river water is so loaded with sediment as to be unfit for bathing as well as for drinking purposes. And it is probable—although not proven—that it at times contains organisms or substances capable of producing diarrhœa in persons not accustomed to its use, and the typhoid bacillus is not absolutely excluded from it, although it has never been actually found in it."

In this connection, however, Dr. Kober calls attention to the fact that, though the specific germs of typhoid fever have never been demonstrated in Potomac water, it is equally true that they were not demonstrated in a well in the suburbs of Washington which had infected eleven persons and in which only the colon bacillus was found. Finally, he thinks that all should be warned against drinking the Potomac water at any time of the year and that much of the immunity from typhoid fever in the northwest section is due to the use of domestic filters and sterilization of the water. This report seems to justify the following conclusions:

1st. Typhoid fever has increased with almost uninterrupted uniformity in the district during the past twelve years, indicating the persistence of local causes.

2d. Typhoid fever is more prevalent in the suburbs and in unsanitary portions of the district, indicating the encouraging fact that the causes are largely preventable.

3d. The rate of typhoid fever cases in certain parts of the city, like the northwest, is no greater than in some of the most healthy American cities.

4th. The majority of persons attacked were consumers of well water, much of which was found contaminated and none above suspicion.

5th. A large percentage of the cases occurred in houses supplied with box privies, which, apart from being an important cause of soil pollution, are be-

lieved to be otherwise instrumental in the dissemination of germs, chiefly through the agency of flies.

6th. While the Potomac water compares favorably with that of other rivers as regards purity, no water supply from streams once polluted can be considered safe for drinking purposes without filtration or sterilization.

Dr. Kober makes the following recommendations, which are of great interest and importance:

1st. The immediate closing of every well in the district wherever a better water supply can be obtained.

2d. The early completion and extension of all necessary sewers within the city limits, and the enforcement of the law to make sewer connections.

3d. The abandonment of all box privies within the city limits and the enactment of more stringent laws for the prevention of soil pollution, together with a rigid, frequent, and systematic inspection of all box privies in the suburbs.

4th. The improvement of the Potomac water by means of filtering-basins, and the extension of this water supply to the suburbs at the earliest moment practicable.

5th. Such measures as may be necessary to improve the sanitary condition in the lower part of the city along the Potomac and the Eastern Branch, looking to the reclamation of stagnant and polluted marshes and the prompt disposal of the sewage.

6th. The enactment of a law requiring notifications to the health officer of all cases of typhoid fever and other infectious diseases in the District of Columbia, together with a rigid enforcement of the building-regulations requiring the cementing of cellars and basements to prevent contamination of the air from polluted subsoils, and the systematic inspection of dairies.

In the mean time, as a preventive measure, he earnestly recommends to the public the thorough disinfection of the excreta from all typhoid-fever patients, and greater care on the part of those connected with the sick, together with the boiling of all water and milk supplied.

SEPTICÆMIA FROM SEWER GAS.

COMMENTING upon the expression of Dr. Jacobi of this city that sewer gas is not nearly so injurious as is generally supposed, and that the various diseases attributed to it are conveyed to the patient in other ways, Dr. A. Lapthorn Smith, of Montreal, says that he has every reason, from his own clinical experience, to think that Dr. Jacobi underestimates the danger of septicæmia from sewer gas. He refers in this connection to the remarkable immunity from puerperal fever at the Preston Retreat in Philadelphia and at the Sloan Maternity in New York, in which institutions there is not a sewer pipe in the building proper. He notes, too, in several outbreaks of diphtheria in Montreal and other cities, the curious fact that the greatest percentage of cases occurred in the houses of the rich, in which many of the rooms were provided with the questionable luxury of permanent marble basins. It seems that in the New York Woman's Hospital there was a high death-rate after cœliotomy

and frequent failure to heal by first intention, until the pavilions were removed from the expensively drained main buildings, when the results immediately began to improve. Dr. Smith states that one of the foremost surgeons in Canada lost his first nine cœliotomies, which were done in a well-drained hospital, and it was not until he operated in a separate building devoid of all plumbing that his results improved. He gives several experiences from his own practice. In a number of operations he had constantly recurring high temperatures in his patients, notwithstanding every possible precaution. Complaint was made to the authorities and it was only after much persuasion that the plumbing was examined, when, with the smoke test, a stream of smoke was seen to emerge from a three-inch hole in the concrete floor of the laundry, and on further investigation it was found that this hole connected directly without any trap with the soil pipe running into the sewer. The defect was remedied, with the result that all wounds healed, as a rule, by first intention, and there was rarely, if ever, any high temperature in the obstetrical ward.

In another case the patient was wealthy and the house in which her confinement took place was provided with the very best sanitary arrangements. The patient for some extraordinary reason—every possible precaution had been taken—was attacked on the fifth day by a chill and rise of temperature, and puerperal fever developed. After careful investigation a crack in the soil pipe of the water closet just above the floor was found from which there was an escape of sewer gas. In view of these and other cases, Dr. Smith is satisfied that there should be an annual testing of the plumbing of hospitals and private houses where women are to be confined or subjected to abdominal surgery, and that all such operations should be performed in pavilions where there is no plumbing whatever. For his own part he says he "would much rather do a cœliotomy in a woodshed or hovel where there was no plumbing of any kind than in the finest hospital operating-room where there was a connection with the sewers of a great city, owing either to a defect in the plumbing or in the siphonage of the trap."

ANTI-VIVISECTION IN CONGRESS.

WE have already referred to the fact that a bill has been introduced into the Senate and House, entitled "A Bill for the Prevention of Cruelty to Animals in the District of Columbia." The bill provides that "no person shall perform on a living animal any experiment calculated to give pain to such animal, except subject to the restrictions hereinafter prescribed." The restrictions imposed by the act are five in number, and are so elaborate that, according to Dr. Busey, who appeared before the committee to oppose the bill, the proposed law would practically prohibit instead of regulate the practice.

An examination of the bill shows that it would quite prevent all experimentation in bacteriology, and would compel the use of an anæsthetic for every hypodermic given to animals. Furthermore, it pro-

vides that the commissioners of the District of Columbia shall appoint agents of the Humane Society who will act as special inspectors, and it is in the presence of some agent of the Humane Society that all the experimental work of the scientific men of the District of Columbia will have to be done. We would not, at any time, oppose the restriction of vivisection if it were needed. But the amount of vivisection in this country is so trivial that it has seemed a waste of legislative and executive energy to attempt special regulation. The cruelties of vivisection, compared to those of sport and the slaughter houses, are as one to millions, and we have always urged the hysterical people who are so frantic over nothing to attend to what is seriously brutal before devoting their time to alleged evils in a work extraordinarily beneficent.

In the present case, the bill for regulating vivisection in the District of Columbia ought to be vigorously opposed by every person who cares for the progress of human knowledge and who has a spark of philanthropic feeling in his breast. The evil that would result if vivisection were entirely abolished is something appalling to contemplate. Let those who do not believe this take a survey of the history of tuberculosis, rabies, antisepsis, and diphtheria in the last ten years.

STATE MEDICAL EXAMINATIONS.

A COMMITTEE of the State Board of Medical Examiners met in this city on the 15th inst., and listened to arguments regarding the question of divided examinations. It seems that the graduates of those New York medical colleges whose courses are graded are not very fresh in the studies of their early years when they get their final diplomas; consequently they object to going before the State Board and being examined upon anatomy, physiology, and chemistry, together with the later studies. The medical students, naturally perhaps, would like to study anatomy a couple of years, pass their examinations in college, then pass them before the State Board, and thus have the whole thing finished and out of their minds. At the meeting of the committee last week Dr. McLane, representing the College of Physicians and Surgeons, and Dr. Daniel Lewis, president of the State Board of Health, spoke in favor of the retention of the present law. Dr. Waite, of the Homœopathic College for Women, and representatives of the Long Island College Hospital and of the University Medical College, spoke in favor of the change. One objection made by those who are opposed to any change was that divided examinations could not easily be made to apply to students who came from foreign countries or from other States. In answer to this, it was proposed that the law be made to apply only to the graduates of medical colleges of this State.

The present law has been working very satisfactorily, and we must express the decided opinion that no change is required or should be made. The medical colleges of the State are showing a petty spirit in their continual protests and attempts at amending the

medical examining laws. They might more profitably spend their energies in trying to teach their students to be better doctors, rather than in fighting for laws which make it easier for their graduates to become licensed. The interests of the State demand that we should have physicians who have been well educated, and are familiar with the fundamental branches of medicine. There is no particular reason why it should admit as medical practitioners men who have forgotten their anatomy, their physiology, and their chemistry. Looking only at the interests of the public and of the profession at large, we think that the present law is a proper one, and makes quite sufficient allowance for the defects in medical training for which some of the medical colleges are responsible. The State medical examinations are not very severe. Let the medical colleges train their students up to the standard required. Their hospital facilities are now ample for the purpose.

News of the Week.

Nevada State Medical Society.—At the semi-annual meeting of the Nevada State Medical Society held at Virginia City, Nev., January 13, 1896, the following officers were elected for the ensuing year: P. T. Phillips, M.D., of Reno, *President*; P. Manson, M.D., of Virginia City, *Vice President*; T. P. McDonald, M.D., of Virginia City, *Secretary-Treasurer*. The next meeting will be held at Reno, Nev., July 13, 1896.

Treatment of Diphtheria in France.—M. Monod, the officer of health to the French Home Office, in a recent report gives the number of deaths from diphtheria in the one hundred and eight large towns (with over twenty thousand inhabitants) of France in the first six months of 1894 and 1895—that is to say, before and after the introduction of the antitoxin treatment. The returns not only denote a very great diminution, but one that is constantly progressing, from fifty-six per cent. in January to seventy-four per cent. in June. The number of deaths from diphtheria in these one hundred and eight towns in the first six months of 1894 was 2,626, and in the same period this year 904.

Admission of Women to German Universities.—The *Hamburgische Correspondent*, speaking of the increasing interest shown in Germany in the question of the rights of women, says: "The women's rights agitation now vigorously going on in England is being watched with the keenest interest in Germany, where also the question is a burning one. As regards the establishment of a German university for women, the well-known Berlin professor of law, Dr. Dernburg, holds that women who have the requisite capacity for academic study have also the right to it, but that it is quite another question whether it would be wise to admit both sexes indiscriminately to the German universities. He thinks it would be better to reserve one of the universities mainly for women—Giessen, for instance, which is beautifully situated in the middle of the empire."

Dr. John De Haven White, one of the earliest of American dentists, who died recently in Philadelphia at the age of eighty-eight years, was left an orphan at the age of seven years and bound out to a farmer, but managed to acquire a fair preliminary education and in 1836 entered the Jefferson College at Philadelphia, studying medicine. At the same time he studied dentistry under Dr. Blankman. In 1852 he established the Pennsylvania College of Dentistry at Philadelphia, the outgrowth of a society which he had been instrumental in forming in 1845. He received the degree of M.D. from Jefferson College and of D.D.S. from several colleges. He also received degrees from foreign universities.

New York Red Cross Institute.—The New York Red Cross Institute was incorporated February 15th. The principal office of the society is to be in New York City, and it is formed to establish a corps of physicians, surgeons, and nurses for attending the sick or wounded of all nations, creeds, and sexes, in time of peace or war, and to supply the association of the American Red Cross with nurses, medical and surgical aid, and assistance. The directors are: Victoria Raymond, C. H. H. Cottrell, Page C. Dennis, A. Monae Lesser, M.D., Bettina A. Hofker, H. G. Steger, M.D., S. E. Barton, C. R. Ellison, M.D., and Robert W. Johnson, all of New York City.

Seeing through Opaque Objects.—Professor Salvioni is reported to have invented an instrument which enables the human eye to see through opaque objects. The instrument consists of a cylinder of cardboard, the inner surface of which is coated with a material that becomes fluorescent under the action of the Roentgen rays. The lens is at one end of the cylinder. The object to be examined with its coverings is placed between a Crooke's tube and the cylinder; on looking into the tube through the lens the observer sees the outline or shadow of the concealed object, which is thrown on the fluorescent interior.

Sale of Brandy Drops an Excise Violation.—Chief Conlin has ordered policemen to visit the candy shops on their posts and instruct the proprietors that they must not sell brandy drops or other confections containing alcohol or intoxicating liquors. Those who persist in selling such confections will be prosecuted for violating the excise laws.

Errata.—In Dr. Beck's article, page 219, under "Prognosis" read: "Experience leads me to conclude that the prognosis of subphrenic abscess, *except those* of malignant origin, such as carcinoma pylori, for instance, depends almost entirely upon early diagnosis." Also *moss* board should be the material used for absorption and not pasteboard.

On page 119, tenth line, Dr. C. Drew's article, the word "light" should read "color."

Surgeon-General H. D. Pickman, of Montana, died January 24th, in Nova Scotia, whither he went for a change of climate.

Urea as a Diuretic in cirrhosis of the liver is recommended by Klemperer.

The Fifteenth Annual Report of the New York State Board of Health has just been published, and it contains a large number of interesting papers and discussions. The sanitary organization of New York State is far behind that of Massachusetts, and the publications of our health board are necessarily much less complete and valuable, but we are glad to notice a gradual improvement. The report refers, among other things, to the epidemic of typhoid fever at Middletown, Conn., caused by eating freshened oysters, and it is recommended that a general prohibition of the freshening of oysters be ordered. If this process is necessary, it is advised that artificial floats be employed for the purpose. The subject of bovine tuberculosis is discussed at much length. The report shows the danger to the health of the people from this cause, owing to the very wide extent of the disease in the State. It is estimated that to destroy all the animals affected would cost nearly one million dollars. We agree with the health board that it would be a wise economy to appropriate this sum, or even a larger one, in order to stamp out bovine tuberculosis and provide such measures as would prevent its future development. The State may profitably spend less money on its capitol or its canals, and more on the organization of its sanitary system. The examination of drugs has been continued by Dr. Tucker, chemist to the board. There have been very few prosecutions of pharmacists who have been found guilty of dispensing impure drugs; hence the facts showing that adulterations do exist have made practically very little difference in the work of the druggists. There have been fifty-three samples of potable water received and analyzed. Many requests have been made for bacteriological examination of waters, but the facilities have not been provided by the State. The chemist asks that such facilities be thus supplied. This, however, should be done only under certain restrictions. It is not the business of the State to do bacteriological and chemical work *gratis* for private individuals or corporations able to pay.

The Orange Memorial Hospital is to have a new pavilion for consumptives, built by Mr. Frederick M. Shepard as a memorial to his son.

The Illinois Supreme Court has decided that physicians cannot be compelled to report upon contagious diseases or render other service to the public without pay.

Investigation of Yellow Fever by Cuban Physicians.—The Spanish government at Havana has appointed a commission to investigate the yellow fever of that island. The commission is composed of medical officers of the army and navy and of prominent physicians of Havana. Bacteriological examinations will be made.

The "X" Rays.—Reports regarding the investigation of the "X" rays and their use in medicine and surgery continue to be published, but no very remarkable results have yet appeared. In Berlin Professor Bergmann performed a minor surgical operation on the hand of a patient for the purpose of removing a shot.

A photograph of the hand by the "X" rays had shown the position of the shot, which had been previously probed for without success. Professor Bergmann stated that there was no likelihood that this form of light ray would ever contribute such benefits to surgery as the discoveries connected with antisepsis had done, and he also cautioned the students against attempting to remove foreign bodies which were not doing any harm.

German Measles is said to be now quite prevalent in certain parts of the city. The total number of cases of measles reported for the week ending February 8th was 432. This number, we understand, includes both the ordinary and the German measles, no distinction being made by the health board between the two. The number of deaths from measles reached a very high figure four years ago, it being 864. The epidemic influence then dropped very rapidly to 393 in the year 1893, but rose again in 1895 and now seems to be increasing.

The Bertillon System.—The use of the Bertillon system for identifying criminals is recommended to the police department of this city, and is likely to be adopted. It certainly ought to be. The old-fashioned method of depending on photographs, certain general facts about height, weight, and complexion, belongs to a much more primitive era than our own. The merit of the Bertillon system has been abundantly tested, both abroad and in some parts of this country. Its value depends upon the practical fixity of the skeleton after the twentieth year of age, the great diversity of dimensions which this skeleton presents, and the facility and precision with which certain dimensions of the skeleton can be measured and recorded.

The Results of the Bacteriological Examinations of 1,000 cases of suspected diphtheria have just been reported in the *British Medical Journal* by Drs. R. T. Hewlett and Harold Nolan. The writers state that the diphtheria bacillus was found in 587 cases, in 409 it was not found, and in 4 cases the organisms were not identified. Thus, in two-fifths of the cases sent in for investigation in London, diphtheria is not found.

A New Treatment for Metrorrhagia is advocated by Henocque and Ardouin. It consists in the application of a mixture of equal parts of salol and antipyrin, using a small tampon of absorbent cotton.

Degeneration.—Dr. D. G. Brinton recently read a paper before the anthropological section of the Academy of Natural Sciences at Philadelphia, in which he endeavored to show that the modern American woman is less capable of child-bearing than the women of the less civilized races, and that anatomical and physiological changes of a degenerative character were at the basis of this.

The Ladies' Home Journal announces that it will no longer receive advertisements of medical preparations. If this is a bid for the doctors' vote, the paper ought to have it.

A Case of Acromegaly improved by treatment with "pineal extract" is reported by Dr. W. J. Hadley in *The Clinical Journal*. Dr. Hadley must have mixed up his glands and written (or used) "pineal" instead of "pituitary."

Anti-Syphilitic Serum is placed on the market by an English firm.

An Acrimonious Debate Over Sugar and other carbohydrates is going on between Dr. Pavy and Dr. Noel Paton. Dr. Pavy believes the liver to be sugar-destroying and that the carbohydrates of the system are made from tissue metabolism. Dr. Paton, who denies this, is behind in his vocabulary of obfuscation but somewhat ahead in his science.

The After-History of the First Case of Myxœdema, Treated by Thyroid Extract.—In the *British Medical Journal* of February 8th Dr. George R. Murray, who first instituted the treatment of myxœdema by thyroid feeding, gives a further report of his first case. The patient was a woman aged forty-six, who had had myxœdema for four or five years. Treatment was begun in 1891 and has been continued ever since. The patient is still perfectly well.

The Medical Times and Register, which has undergone various vicissitudes, is now a bi-weekly and appears in a new and improved dress.

Golfer's Arm.—Mr. Fred. Edge, F.R.C.S., writes to the *British Medical Journal*: "After playing double my usual rounds at golf on December 31st, I awoke next morning with great pain in my shoulder and arm. This has gradually improved but still persists, and seems entirely confined to the musculo-spiral nerve. There are painful points where the nerve pierces the external intermuscular septum and the fascia about the elbow, and numbness with tingling in the dorsum of the thumb and first finger, not of the second. Having met with another case which has persisted for ten months and finding that it entirely spoils one's enjoyment of golf, it has seemed worth while bringing the subject to your notice. It appears to be due to the repeated sudden and whip-like contractions of the triceps bruising the musculo-spiral nerve, and I think it arises when the tone of the muscle is defective, and consequently the change from rest to contraction is more marked. Very graduated exercise and fresh air with gentle friction of the arm relieves the condition permanently."

An Epidemic of Influenza is prevailing in Philadelphia. The *Philadelphia Polyclinic* states that in connection with the influenza there develops an insidious form of pneumonia with a strong lethal tendency. This fact has been observed in previous years when the epidemic was prevailing.

Against Tall Buildings.—Senator Pavey, of the New York legislature, has introduced a bill providing against the future erection of tall buildings in New York City.

City Hospital.—Dr. Alfred N. Strouse has been appointed attending ophthalmologist to the City Hospital.

The Ringing of Bells.—The Health Commissioner of Brooklyn has sent a communication to the pastors of churches having bells warning them that there is a sanitary ordinance which expressly prohibits the ringing of large bells in such a manner as to become a prejudice or peril to the life or health of any human being. All church authorities and others having control over the ringing of large bells in neighborhoods that are thickly settled are, therefore, requested to prevent bell ringing before 7 A.M., and in localities where complaints of invalids are brought to their notice to restrict the bell-ringing in the daytime to as few strokes as possible.

The Question of the Increase of Intemperance.—At regular intervals we are told that intemperance and the consumption of alcohol in various forms are increasing, and then come statements which assert the direct opposite. Recently Mr. Whyte, of the United Kingdom Alliance has issued a letter, in which he states that laborers lose 10.9 per cent. of their numbers from drunkenness or alcoholism; artisans, 13.1 per cent.; the independent classes, 20.4 per cent.; the mercantile, 13.8 per cent., and the tradesmen, 16.9 per cent. He infers from this that sobriety is not increasing, as has been stated, in the middle and upper classes, but rather the contrary, and that the working classes really suffer less from alcoholism than the better educated. Mr. Whyte's figures are based upon a study of 4,200 cases collected by an investigating committee.

Plagiarizing Again.—We had supposed that American authors were rising above the moral plane which prompted them to appropriate the writings of others, and that the medical profession especially had kept themselves clear from this disgrace; but the *Medical Press and Circular* of February 5th, published in London, contains the following:

"As evidence of the dishonesty to which English authors are subject, we need only mention the case of a 'System of Surgery by American Authors,' recently issued. On receipt of the first volume in this country the American system of surgery was discovered to be most pronounced in its absence, and English authors had been so plagiarized that the sale was prohibited in Great Britain and the volumes had to be promptly returned to the home of their birth. Of course, this might have been a mere coincidence, and the American authors might not have known of the existence of the English works, but they will, perhaps, pardon our suggesting that it would have been more straightforward had they issued the work as an American system (not in surgery); we should have understood it here."

Besides the American "System of Surgery," published by Lea Brothers & Co., of Philadelphia, we learn that Nancrede's "Essentials of Anatomy," published by Saunders, also of Philadelphia, and Leonard's "Vest-Pocket Anatomist," published by the author in Detroit, are open to the same criticism, and the sale of the three books has been stopped in England. It would seem that the course of both authors and publishers in these cases demands an explanation.

A World's Congress of Medico-Climatology will be held in San Antonio, Tex., beginning February 20, 1896, and continuing for three days. This meeting is to be called a "national meeting." The international meeting of the congress is to be held every fifth year.

Revised Edition of the History of the War.—A committee appointed by the Indiana State Medical Society has drafted a series of resolutions "appealing to Congress for the authorization of the publication of a revised edition of the "Medical and Surgical History of the War." It is stated that the first edition was limited in number and that very few Southern physicians received copies.

Medical Legislation in Ohio.—The Mosgrove-Kimmel bill providing for the regulation of the practice of medicine in Ohio has passed the house of Representatives by a large majority.

Insanity and Murder.—The Supreme Court of the United States has just handed down a decision which is of much importance in cases involving a question of the insanity of murderers. The court has reversed the decision of the inferior court and lays down the principle that the burden of proof of guilt rests in all criminal cases upon the prosecution; in other words, the prosecuting attorney, in cases where the claim of insanity is put up, must prove that the accused is not insane.

Chloroform and Oxygen.—The use of oxygen in combination with chloroform in anæsthesia originated, according to the *British Medical Journal*, with Neudörfer and was in vogue in Vienna about ten years ago. Bertel, in a communication to the St. Petersburg Medical Society, asserted that more rapid and successful anæsthesia followed its use. A number of other Russian surgeons have employed it. The European surgeons, however, apparently have used chloroform in connection with the oxygen.

A Sure Cure for Alcoholism.—We prefix the foregoing head to this item with a full consciousness of the significance and interest which such a title will excite. There is, however, no doubt that a sure cure for alcoholism exists, and it is now being used and exploited at much length by Dr. E. Marandon de Montyel. Dr. Montyel's cure for alcoholism is total abstinence from alcohol! He has collected 12,067 cases of drunkards, of which 5,550 were cured, and they were cured by not being allowed to drink.

The University Medical Magazine, while not opposing the use of Greek as an international scientific language, thinks Latin would be the better medium. Almost every educated person has studied some Latin and usually more than he has Greek. Its use would not require a separate font of type, because the characters in the Latin and English alphabets are similar. "Latin," it adds, "was the scientific language of the world for nearly seventeen hundred years, and it is less than two centuries since it ceased to be the common language of science." The Latin language allows of clear, terse, exact statements, technical terms can be easily manufactured from it, and new compounds de-

vised whenever needed. In other words, the language can be made elastic enough to suit the common purpose. In order to make the Latin colloquial it must be taught in the schools by persons who are able to speak the tongue.

The Academy of Medicine of Cincinnati on January 20th passed a resolution to the effect that all members of the academy be requested not to enter into verbal or written contract or agreement with any lodge, club, society, or organization, to render professional service to the members of such lodge, society, or club, or to the wives and families of the members thereof. This resolution is aimed at a growing tendency to form syndicates, societies, and institutions by which people can be treated wholesale at low rates. There has, no doubt, been developed a great deal of abuse by reason of this practice, and while the position taken by the Cincinnati Academy is rather radical, it will, we believe, serve a useful purpose in calling attention to the evil of cheap clubs and cheap provident associations.

Public Bathing Facilities for Brookline.—The town of Brookline, Mass., on January 30th appropriated \$40,000 for the purpose of furnishing free public bathing facilities to its residents.—*Boston Medical and Surgical Journal*.

Precautions Against Rabies.—In view of the notice recently published by the State Board of Health of Massachusetts that rabies was present in certain cities and towns about Boston, including Somerville, the Somerville board of health has published the following regulation:

"No dog shall be permitted to go at large in the city unless securely muzzled with a proper-fitting wire muzzle. Dogs shall remain so muzzled for a period of ninety days dating from January 23d. No person shall during the continuance of this order permit any dog owned by him, or which is in his possession or control, to go at large within the limits of Somerville unless the dog is at all times securely muzzled."

The punishment for disobeying a rule or regulation of the board of health is a fine not exceeding \$500 or imprisonment for a term not exceeding one year.—*Boston Medical and Surgical Journal*.

The New York State Lunacy Commission.—Aside from the special features of the report, something may be said in regard to the defence of the general policy of the commission as stated at the beginning of the volume. It seems to be exercising the functions of a board of control, together with those of advisory medical and medico-legal supervision, and the tendency would seem to be ultimately to supplant and abolish the local boards of management. The combination, in a close board of only three members, of the business control with the other and higher functions of a lunacy commission is an experiment that has not heretofore been a brilliant success, and there is a danger, in our opinion, of an undue predominance of a "business" spirit over the higher professional and scientific one. The ideals of the two are not in the same line, and while the former is per-

haps the one most readily appreciated by the mass of the public, the latter is that which should be the aim of a body that is to have their fullest confidence. The titling of mint, anise, and cumin tends sometimes to a neglect of the weightier matters of the law. Of course everything will depend upon those who are to carry out the objects of the lunacy commission. Upon their scientific spirit and judicial fairness, their correct judgment and strict sense of propriety and honor, as well as upon their absolute integrity, everything really depends. It is to be hoped that these points are duly appreciated by the New York Lunacy Commission in the difficult and complicated task they have assumed.—*American Journal of Insanity*.

The Forthcoming International Periodical Congress of Gynecology and Obstetrics.—The second session of this congress is to be held at Geneva, Switzerland, in the first week of September. In the section for gynecology the following is the official programme: (1) "Treatment of Pelvic Suppurations"—Reporters: Dr. Bouilly, of Paris; Dr. Kelly, of Baltimore; Dr. Zweifel, of Leipsic. (2) "Surgical Treatment of Uterine Retro-Deviations"—Reporters: Dr. Küstner, of Breslau; Dr. Pozzi, of Paris; Dr. Polk, of New York. (3) "What Method of Closing the Abdomen Presents the Best Guarantee against Abscesses, Eventrations, and Hernias?"—Reporters: Dr. Granville-Bantock, of London; Dr. La Torre, of Rome. The Massachusetts Hospital for Dipsomaniacs and Inebriates sends out its fourth annual report, which presents a striking contrast to the reports of the Keeley cures as regards temperateness of statements concerning patients treated. There were, for example, during the year 1894-95, 121 patients discharged from the hospital. The condition of 106 of these is reported upon; of these, 27 are reported as doing well or abstinent, 10 as improved or drinking less, 22 as unimproved or drinking as much as ever, while 47 had returned to the hospital. This shows that the percentage of those that are spoken of as "doing well," which would be ordinarily reported "cured," is about twenty-five per cent., and this may be taken as a fair estimate of the results of hospital treatment for dipsomaniacs and inebriates. A further table is given, showing the apparent habits of persons who had been out of the institution for one year. A total of 121 persons is reported upon, and of these twenty-six per cent. are reported "doing well," and eleven

per cent. improved. As to those who relapse and return to the hospital, we are told that the relapse usually occurs within two years from the time of leaving the institution and that the tendency to relapse seems to decrease with time. The trustees report that the question of compulsory confinement of dipsomaniacs in institutions is being more actively agitated and advocated every year. There is as yet no law in any European country which makes the confinement of inebriates compulsory, but such laws are being recommended, and in Austria, England, and France the trend of opinion seems to be increasingly in favor of them.

Risks of Anæsthesia.—According to the *Medical Press*, sixty-one deaths have occurred during the administration of anæsthetics in the United Kingdom in the past year. Fifty-two of these have been due to chloroform.

Through the Activity of the Decimal Association, a committee of the House of Commons has made a report advising the adoption of the metric system in England, and it further advises that after a lapse of two years the metric system be rendered compulsory by act of parliament. A similar resolution in favor of the metric system has been referred to a committee of the House of Representatives at Washington.

The Woman Doctor Could Not Come.—It was at the time when, in Baltimore at least, the woman doctor had just appeared upon the scene, and *à propos* of woman's usefulness and her limitations in this new field the late Dr. W. C. Van Bibbert told this story: Awakened late one night by a ring at his bell, he called down the speaking-tube to know who it was. "It's I, doctor, Mr. ——. I want you to come at once to my wife. She is in labor." "Yes, but I don't attend your family. Why don't you go for your own physician?" And back came the reply: "I did, doctor; but she's about to be confined herself."

Congenital Erosion of Cervix Uteri.—At the stated meeting of the College of Physicians, Philadelphia, held on February 5th, Dr. Charles B. Penrose read a paper entitled "Congenital Erosion and Split of the Cervix Uteri," in which he pointed out the occasional existence in virgins and sterile women of conditions that might arouse a suspicion of previous pregnancy and delivery. The lesions had previously been studied by Leopold and Fischel in infants. Dr. Penrose reported several cases in women in whom the existence of prior pregnancy and delivery was excluded. The matter has obviously important medico-legal significance and is eminently deserving of further investigation.

Surgical Injury to Ureter.—Dr. J. M. Baldy at the same meeting read a "Report of a Case of Surgical Injury to the Ureter," in which, in operating for the removal of a cystic tumor from the abdominal cavity, one of the ureters was divided, continuity being restored by drawing the proximal extremity of the ureter through an incision into the bladder and attaching it by suture

to this viscus. Dr. Penrose referred to a similar case in which, in the course of an operation for the removal of malignant disease of the uterus, a ureter was intentionally divided, functional relations being re-established much in the same manner as that described. Drs. B. F. Baer and E. P. Davis read a joint paper on "Cælio-Hysterectomy for Impossible Labor, with Intrapelvic Subperitoneal Treatment of the Stump," Dr. Baer dealing with the "Technique of the Operation" and Dr. Davis with the "Choice of Operation." Dr. P. H. Pye-Smith, of London, was elected to associate fellowship.

Wanted to Levy on the Baby.—A colored midwife called on a Gallatin, Tenn., physician, last week, and said she had "stayed all night with a woman in labor, and the promised fee had not been paid." She wished to know if she had a legal right to take the baby away from its mother and keep it until the bill was forthcoming. The doctor admired her forethought and thought the theory an ingenious one, but practically it would be a dangerous precedent, as such a custom might become a law, in which case every doctor's home would soon be an orphan asylum.

French Gallantry.—The physicians of Montreuil, near Paris, refuse to give their services to the municipal dispensary because a woman has been appointed to serve in it one day in the week. Their grievance is aggravated by her being paid, while their services are given free.

Music and Bald-Headedness.—The *Boston Medical and Surgical Journal* calls attention to the fact, which it says is demonstrated by an English statistician, that music has a wonderful influence on the growth of the hair. This statistician has discovered baldness to be prevalent in twelve per cent. of composers, which is about the average for people in general. Instrumental performers, however, almost always retain their hair up to an advanced period of life. Players on the piano and violin have particularly good heads of hair, and the aggressive example of Paderewski at once comes into one's mind in support of this assertion. On the other hand, brass instruments have a fatal influence on the growth of the hair, notably the cornet, French horn, and trombone. The baldness which prevails among members of regimental bands has been given the name of "trumpet baldness." Our contemporary does not venture to explain this curious phenomenon, but simply quotes these facts. If well established no doubt they will give a tremendous impetus to the use of the piano and violin. Doctors, it adds, are the baldest of all professional men, the percentage being thirty.

Died from Taking His Own Medicine.—We predict a large number of more or less wise and satirical observations in connection with the tragic death of Mr. John Robinson, a practitioner living in Yorkshire, England. Mr. Robinson had a patient for whom he prescribed what he believed to be a simple remedy. The patient took a dose and returned, saying that it made him ill and refusing to take more. Thereupon Mr. Robinson put up another bottle and the patient

went away, but returned the next day with the same story. The doctor then told him that the medicine was something that he prescribed often, that it was quite harmless, and that he himself would be willing to take the contents of a whole bottle at once. He called for some water, poured out a large dose of the mixture, and swallowed it—and in two hours was dead. It is supposed that tincture of aconite took the place of what the doctor thought was tincture of ginger.

The Female Medical Students in India have been presented with a hotel which is to be used as a residence for them during term time. One of the Indian officials has given 25,000 rupees to the fund for its support.

The Dangers of an Eclipse.—A German paper published recently a curious official proclamation printed at Ehrenbreitstein on the Rhine on July 22, 1748, warning the populace against the dangers from the impending eclipse of the sun, and giving directions to keep wells covered and not allow cattle to go to pasture on the day of the eclipse because of the poison which would then fall from the sky.

A School of Medicine in Odessa.—The city of Odessa has voted an appropriation of nearly half a million dollars for the establishment of a medical faculty in connection with the university of that city.

Obituary.

JOHN HOWARD RIPLEY, M.D.,

NEW YORK.

It is with an inexpressible sadness of heart that we are called upon to record the death of our old friend and hospital colleague, Dr. John H. Ripley. Taken away in the prime of his great usefulness and in the full fruition of high professional accomplishments, his great loss will be keenly appreciated by the large number of medical associates who were accustomed to counsel with him in times of great emergency and to value his matured opinions in the division of weighty responsibilities. He occupied a peculiar and distinctive position in the medical history of New York, in that he exemplified a leading type of the old-fashioned, all-around medical practitioner, who was at home in every sick-room and whose broad views of pathological laws could be readily and effectually applied to the most difficult and most obscure cases in the widest range of general medicine and in the rapidly progressive practice of operative surgery. A close and diligent student, with well-trained habits for systematic work, his thoroughness in the examination of cases was an object of admiration with all the professional men who so eagerly sought his advice and who so implicitly relied upon his judgment. His well-earned reputation in this line brought him in frequent consultation with leading specialists, and his opinion, often stubbornly maintained in the face of heavy odds, frequently won for him the victory over his opponents. While ever ready to accept new views and follow the advances in the different lines of progressive investigation, there was always a balance of judicious conservatism that made him a safe adviser and an efficient helper. Few could grasp more readily and effectually the salient points of a case, and none could impress them more directly upon the student at the bedside. His numerous hospital pupils

gratefully testify to his marked ability in this direction and willingly accord to him the high distinction of a model clinical instructor. It was this particular faculty that eventually gained for him a large consultation practice, not only in this city but throughout wide districts of the surrounding country. It was during one of his later consultation visits to Hartford that he was seized with the first symptoms of grippe, which finally ended in the complication causing his death. He was on his return journey in the cars, when he was seized with dizziness followed by a chill and with much difficulty succeeded in reaching his home. With characteristic pluck he made light of his ailment, and, notwithstanding the depressing effects of the attack, he bravely kept at his work until at the end of three weeks he was forced by the advice of his medical friends to seek recuperation in the warmer climate of Florida. Three weeks ago he started for Orma in that State, and then for the first time gave himself to the long-neglected care of his health. The change was beneficial for a short time only. On February 14th a rheumatic complication showed itself, attended with frequently recurrent chills. Endocarditis supervened; his heart, already crippled with double valvular disease, being unequal to the extra strain, he passed away quietly on the evening of February 15th. His last hours were made peaceful by the presence of his loving wife, whose companionship was a condition of his absence from home. The remainder of his family consists of a son and two daughters.

Dr. Ripley was born in South Coventry, Conn., on May 16, 1837. After a preliminary high-school education in Westfield, a neighboring town, he came to New York in 1861 and entered the medical department of the University of the City of New York. Before finishing his course he entered the army and remained in the service until the close of the war, when he returned to this city and was graduated in the class of 1866. He began practice at once, and soon took a high place among the then younger professional men of his class.

He soon became closely identified with hospital work, which was uninterruptedly carried on for twenty-five years. At the time of his death he was the visiting physician of St. Francis Hospital and honorary consulting physician to the Charity Hospital, which position was given to him in recognition of his effective services. He was also connected as consulting physician with St. Joseph's Hospital and the Hospital for the Ruptured and Crippled. He was a large contributor to the medical literature of the day, both on medical and surgical subjects. The most notable of his articles contributed to the *MEDICAL RECORD* were: "Scarlatinal Nephritis and its Complications," "The Treatment of Croup by Tracheotomy," "Tracheotomy in Bronchocele," "Operative Removal of Drainage Tubes from the Pleural Cavity," and "Noma Following Intermittent Fever." He was at one time clinical professor of the diseases of children in the medical department of the University of the City of New York and in the New York Polyclinic, both of which professorships he resigned because of the demands which his private practice made on his time.

He was also a member of the Medical Society of the County of New York, of the New York Academy of Medicine, of the New York Pathological Society, in whose proceedings he took a very active part; of the Society for the Relief of Widows and Orphans of Medical Men, and of the Physicians' Mutual Aid Association.

The funeral services were held on Tuesday evening at his late residence, 605 Lexington Avenue, and the remains were taken the day following to Westfield,

Conn., to be buried in the family cemetery. And thus, alas! brother, farewell.

At a special meeting of the Medical Board of St. Francis Hospital, New York, the following resolutions were adopted:

"Whereas, It becomes our painful duty to announce the death of Dr. John Howard Ripley, attending physician to the St. Francis Hospital, New York, and late president of its medical board, therefore be it

"Resolved, That the medical board desires to place on record its due appreciation of his long and valuable services to this institution, faithfully and cheerfully rendered for nearly a quarter of a century.

"Resolved, That from his first connection with this hospital he was an ever-willing servant of its best interests, an ardent promoter of its highest aims, and an active participator in all its charitable benefactions.

"Resolved, That his untiring zeal in the performance of his arduous and responsible duties, his wisely conservative judgment, his painstaking accuracy of observation, and his ever available and profound knowledge of clinical phenomena were qualities which commanded the highest respect of his associates and stimulated the emulation of all who share the results of his unselfish labors.

"Resolved, That the remembrance of his manly disposition, his frank manner, his energetic spirit, and his scholarly attainments will ever serve as a cherished lesson from the well-ordered life of a dutiful worker, an indefatigable investigator, and a model physician.

"GEORGE F. SHRADY, M.D., *President*.

"GEORGE M. EDEBOHLS, M.D., *Secretary*."

ALEXANDER S. HUNTER, M.D.,

NEW YORK.

DR. ALEXANDER S. HUNTER died at his home at Spuyten Duyvil on February 14th. Dr. Hunter had practically retired from active work during the last few years, but previous to that he was one of the conspicuous physicians in the city. He was particularly active in the Academy of Medicine as chairman of the section on obstetrics, and for a long time he made that section the leading one in the academy. As president of the County Medical Society he was a most alert and efficient officer.

Dr. Hunter was born at Conesville, N. Y., September 23, 1839. He was graduated from the Albany Normal School, and after teaching for a while he studied civil engineering. He then went to Great Barrington, Mass., where he became professor of mathematics in the Sedgwick Institute.

Then he came to this city and entered the New York University Medical College, from which he was graduated in 1863. He had practised his profession in this city ever since. His work in later years was chiefly obstetrical and gynecological, and in these departments he was very successful.

He was elected president in 1890 of the New York County Medical Society, and was the first president who was reelected to succeed himself since the organization in 1807. He was chairman in 1891 and 1892 of the committee on admission of the Academy of Medicine. For six years he was chairman of the obstetric section of the Academy of Medicine. He was also a member of the New York State Medical Society. For six years past he practised chiefly as consulting physician.

Dr. Hunter was a man of high character, well-trained mind, and an energetic and indefatigable worker. He did a great deal toward the organization of scientific and practical work of the profession, and his death is a loss which will be widely felt.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

AFRICAN FEVERS—DISSEMINATION OF THE DIPH-
THERIA BACILLUS—PROPOSAL FOR A CENTRAL HOS-
PITAL BOARD—A BALNEOLOGICAL SOCIETY—SIR F.
LEIGHTON.

LONDON, January 31, 1896.

THE death of Prince Henry of Battenberg has brought into prominence the subject of African fevers. Not that there was anything unusual in his case, but his prominent position and the bereavement in the royal family excites the sympathy of all classes of the public, who naturally seek to allay their curiosity by acquiring some information from their doctors. I have had to advise a number of persons who were proceeding to Africa as to the precautions they should observe and to consider the detailed records and charts of many cases, not a few unhappily fatal, so that I retain no little interest in the subject. Our losses in Ashantee have been trivial compared with those of France in Madagascar and this we owe to the admirable arrangements of the medical department for the expedition. Before the discovery of the malarial parasite the use of quinine was well known both as a remedy and a prophylactic, and so far as treatment and prevention go no advance has followed that discovery. Recent experience has indeed added something to our knowledge of the prevalence and virulence of malaria over various large tracts of Africa and brought the more intense forms of these diseases into line with those of southern Europe. The milder attacks which occur in the elevated districts become more dangerous as we descend to the coast or into the valleys, and on the West Coast itself the utmost severity is attained in several localities, while here and there the middle type may prevail in even what appear unhealthy coast towns. Like many others who have studied the subject, I am strongly impressed with the value of quinine as a prophylactic and repudiate the notion that the drug is injurious if continued for considerable periods in doses sufficient to keep the disease at bay. Of course proper diet and the avoidance of alcohol, excessive fatigue, and exposure to the tropical sun are important, but with reasonable care and regular doses of quinine I have known long, fatiguing marches undertaken without casualties. I have also known men thus guided to live for years in Africa with little inconvenience, though they have witnessed the deaths of many of their companions. Probably not a little depends on the constitution, for, though no European can reckon on escape, some seem to become quickly acclimatized, while others apparently as healthy and even more robust become early victims, and that too while living under precisely the same conditions and in the same localities and the same houses. We are to have a discussion on the subject at our premier society on the 11th prox.

Drs. Kanthack and Stephens have confirmed the observations of Wright and Stokes, of Booton, that the escape of the diphtheria bacillus into the circulation and organs is not uncommon, at least in fatal cases.

The interesting researches of Dr. Sidney Martin seemed to point the other way and it was too commonly assumed that the bacillus only developed in the false membrane, and the presence of poisonous albumoses in the viscera was supposed to be due to a ferment liberated by the bacillus escaping and converting the proteids into these toxic products. Drs. Kanthack and Stephens in a paper before the Pathological Society report that they found the bacillus in the viscera and especially in the spleen in fatal cases

with laryngeal complications. The pneumonia so common in diphtheria is therefore probably not of pyo-coccal origin, as is frequently assumed, but due to the bacillus which these observers have found in the lungs. It is easy enough to see that there are various ways by which the bacilli may reach the viscera in which they have been found, and now it is shown that they may be widely disseminated the fact explains certain obscure points, while it is really what might have been expected from the usual behavior of bacilli.

A central hospital board for London is a favorite idea with many and Colonel Montifiore advocated it last week at the Charity Organization Society. When the large and opposing interests are considered, it is doubtful whether a really impartial board could be formed, certainly not under the auspices of the Charity Organization Society, which, though it may have done some good, has the name of perpetually interfering or trying to interfere with those charities which decline its assistance. It is easy to imagine that in a perfect state of society much could be gained by a central committee, but as we are the Hospital Sunday Fund exhibits some of our defects in a rather pronounced way. It has come to be worked by the opponents of special hospitals and at times there is an aggravating display of fierce opposition by men who were appointed to be impartial. It might be the same with any other central board, so that the smaller institutions are hardly likely to fall into such another trap. They have been cajoled into giving up some of their own collections and the result has been anything but pleasant to their supporters.

We have now a Balneological Society to add to our long list. I wish it success. It has opened with fair prospects and many doctors at our spas have joined, as well as a few general physicians in London and the provinces. I miss, however, from the first list of officers some names intimately associated with the subject. They should at least have been sought as honorary members in preference to those who have done nothing more in this way than to send a few patients to our health resorts.

The death of Lord Leighton, better known as Sir Frederick Leighton, the genial president of the Royal Academy, has excited much interest, as to the public it naturally appeared sudden. It was known, however, to many that he had for several years been affected with disease of the heart and since 1894 attacks of angina pectoris had occurred. It was an attack of this kind that terminated fatally last Saturday. The distinguished artist retained his consciousness to the last, and it is said that on the last night of his life he dictated a letter for publication expressing his thanks for the numerous congratulations he had received on his elevation to the peerage.

OUR BERLIN LETTER.

(From our Special Correspondent.)

ROENTGEN'S DISCOVERY—INFLUENCE OF BICYCLING ON
HEALTH — THYROID-GLAND TREATMENT — AMEBIC
ENTERITIS.

BERLIN, February 8, 1896.

THE new year has brought us, shortly before the end of the century, something that may truly be called *fin-de-siècle*. All Berlin, scientific and lay, is under the spell of the discovery of the Würzburg professor of physics, Roentgen. The wonderful discovery has been demonstrated at every meeting of our two largest medical societies, the Berliner medicinische Gesellschaft and the Verein für Innere Medicin. Both physicians and public have conceived high hopes that some advantage to suffering humanity will accrue from it. How far these hopes are illusory the future

only will show. The famous discoverer himself, who was recently summoned to give a demonstration in the presence of the Emperor, is somewhat pessimistic and believes that there is danger that its value as an aid to medical and surgical diagnosis may be greatly overestimated.

As so often happens, accident was really the father of this invention. While Roentgen was experimenting with a Crook's tube covered with black pasteboard, he suddenly saw a letter which had been written with barium and platinum cyanide on paper become fluorescent. In following up this to him new phenomenon he found that from the cathode of the tube which had been made luminous by a strong current rays proceeded which made certain bodies, such as barium or iron cyanide, mica, calcareous spar, rock salt, and glass, fluorescent. These rays, which are invisible to the human eye, passed through solid substances, such as pasteboard, gutta-percha, and thick books of a thousand pages, with hardly a diminution of intensity, and only bodies of great specific gravity, such as lead, were impenetrable to the rays. He found that in general the thickness of these bodies was a measure of their penetrability. These rays, which Roentgen has provisionally called "X" rays, are not decomposed by prisms, nor refracted by lenses, nor absorbed by powdered substances, nor deflected by the magnet. In this they are distinguished from the already known cathodal rays of Lenard, which have less penetrating power and are deflected by magnets, and especially from the ultraviolet rays. Roentgen, however, believes that the "X" rays are generated by the cathodal rays in the glass wall of the discharging apparatus, and that they represent the long-sought-for longitudinal oscillations in the ether. Now the property of these rays of exerting a chemical action upon the silver salts through the occasioning of fluorescence in the glass or gelatin layer of dry plates, together with their power of penetrating solid bodies, has produced most wonderful phenomena, pictures from a world of enchantment. A most striking picture is that of the hand of a living person [reproduced in the MEDICAL RECORD of February 15th.—Ed.]. This hand was placed against the wooden slide of a plate holder and both were enveloped in an opaque covering. The "X" rays were now developed in a Crook's tube enclosed in a cardboard cylinder, and these rays passed through all the obstacles and made a negative picture on the plate. In the positive picture the soft parts of the hand appeared as a light shadow, while the bones and a ring on one of the fingers stood out in dark, sharply outlined figures. The practical value of the discovery as a diagnostic aid was shown in one case by the demonstration of a splinter of glass near one of the bones. Sanitätsrat Jastrowitz, Dr. Neuhaus, and others exploited the discovery by means of lectures and demonstrations before the medical societies, while the curiosity of the general public was gratified by lectures given by the director of the department of physics of the Institut Urania. Further details of this epoch-making discovery, especially as it concerns practical medicine, will be given in the next letter.

Another important matter, and one that concerns Americans also, has been the subject of a lively discussion in the medical world here. At the instigation of Professor Leyden, Dr. Martin Mendelsohn recently instituted a scientific investigation concerning the effect upon the human organism of bicycling. Germany, and especially Berlin, as Leyden remarked in the discussion of this subject, is far behind other countries, America in particular, as regards the use of the wheel, and for this reason the question is new and of great interest to our medical men. The speaker was in favor on the whole of a more general cultiva-

tion of this sport, and recommended it especially for those of sedentary employment, whose work requires prolonged sitting or standing. He uttered a warning, however, against overexertion, to which almost every rider was inclined by his ambition to excel others. A wheelman who had ridden six hundred and seventy-three kilometres (four hundred and thirty miles) in twenty-four hours had lost about thirteen pounds in weight. Metabolism is very remarkably increased. The speaker thought the dangers of cycling were especially in its influence upon the heart and lungs. A pulse of two hundred and fifty to the minute has frequently been noted, and cases of sudden death after a very hard ride have several times been reported when the heart was already fatty degenerated. Cardiac troubles, especially dilatation of the right ventricle and irritable heart, are often induced by cycling, yet in many diseases a very favorable influence has been observed. Those who took part in the discussion, and among them were many of the best known among Berlin physicians, did not agree on all points with the reader of the paper. They spoke with special disapproval of the crouching position of the "scorcher," which was asserted to be the cause of phthisis which frequently develops in cyclers. They held that rowing was the best sport, as in that all the muscle-groups were brought into play, and there was no inhalation of injurious dust. Fürbringer compared cycling to hill-climbing, and said that, arguing from his own experience (for he had once, in spite of being already very spare, lost five pounds in a walking-tour among the hills), he could not recommend cycling as a sport, and he would condemn it altogether in any case of heart or lung trouble of whatever nature. Leyden said that wheeling as a convenience and wheeling as a sport ought to be discussed separately. All were unanimous that the wheel was an economizer of time. He had found in travelling that the wheel was used both by laborers and by the members of the highest classes, especially in Copenhagen, where professors even rode to their lecture halls on wheels. He would recommend the use of the bicycle to nervous persons as a means of strengthening their character and their nerves. Placzek took a very decided stand in favor of wheeling. He himself is a wheelman, and he characterized the bicycle as "the best means for reducing the chronic cerebral congestion of brain workers; the best means for awakening in those who have become unaccustomed to bodily exercise an inclination to work through the practice of this form of activity, which quickens both soul and body; the best means, when one would shake the dust of the great city from his feet, of seeking that inner communion with nature which has become almost a thing unknown to the modern man."

A greater unanimity existed in a discussion concerning thyroid-gland treatment. All the speakers, Ewald, Mendel, Senator, agreed with the reader of the paper, Dr. Stabel, that the course of Graves' disease was unfavorably influenced by thyroid extract. In simple goitre, as well as in myxœdema, good results were obtained. A new light on this subject had been thrown by the discovery by Baumann of thyreoiodine, an iodine-containing organic substance. Ewald demonstrated the presence of this body in thyroid tablets. This discovery shows that the old treatment of goitre by iodine was a rational one. The speaker uttered a warning against the misuse of these tablets, the sale of which was unfortunately not regulated by law.

Not only the science of therapeutics, as in this case, but also that of diagnosis has recently been enriched by advances in the direction of a greater knowledge of intestinal diseases. Boas called attention to a little-known form of enteritis caused by the presence of the

amœba. This parasite has up to this time been found once only in endemic dysentery, but Boas has had the opportunity of observing it in two additional cases. A characteristic feature of this so-called amœbadysentery is the constant presence of the amœba in the pea-soup-like, strongly alkaline stools, the property of these amœbas in common with other monads of changing their form, and the obstinate resistance of the disease to almost every plan of treatment. The amœbas in these cases, contrary to what has been observed by Loesch in tropical dysentery, were not infectious for cats, and also enclosed no red blood corpuscles in their substance. They appeared under three forms—the cystic, the resting, and the moving; they varied between 15 and 35 μ in size, and remained alive for from eight to ten hours. In all the examinations the stools were placed at once in the thermostat and the matter was examined on a warmed object glass. Boas also found amœba-like objects in cases of diarrhœa artificially produced by Carlsbad salts, but he doubted their identity with the genuine amœba. He believed that the amœbæ were pathogenic in his cases and not accidental, and he urged all investigators to search for these bodies in all suspicious cases of obstinate diarrhœa.

SHOULD OUR HOSPITALS EXTEND THEIR FACILITIES FOR OPERATING TO SURGEONS GENERALLY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Under the above title an article from the pen of Henry S. Stark, M.D., of New York, appears in the *MEDICAL RECORD* of January 25, 1896, deploring the fact that the physicians of that city are compelled from lack of facilities to refer most of their operative cases to medical men connected with some hospital. He places a question mark after the title and proceeds to argue in the affirmative.

The question has already been answered in the affirmative in Chicago and a statement of the condition of affairs here may be of interest, if not of assistance, to our New York brethren.

Up to the year 1886 the hospitals of Chicago were all close corporations, and no one could treat a case of disease or operate in them unless he was a member of the staff. The writer, seeing that a large proportion of his legitimate fees went into the pockets of others because he was not allowed hospital facilities, provided himself with portable operating and instrument tables, gowns, towels, sterilizers, basins, pitchers, irrigators, etc., so that he might turn any ordinary room into a complete operating-room. By means of these he performed his first fifteen abdominal sections at the private residences of his patients, besides numerous operations for lacerated perineum and uterine cervix, carcinoma of the breast, hemorrhoids, etc., but the necessity of preparing all dressings, sterilizing gowns, towels, etc., himself, besides any number of extra visits at all hours of the night and day to do what in a hospital is done by the interne, rendered the profit small, since the fees had to be the same as some hospital attendant would charge. The results, however, were fully as good as he afterward obtained in hospital practice, his twelfth abdominal section being his first fatal case.

In 1884 the Lakeside Hospital was organized by two Chicago physicians to be devoted to rectal work. In time it was seen that it could not succeed financially and about 1887 the doors were thrown open to members of the regular profession, and they were allowed to treat and operate on their private patients at a cost of from \$15.00 per week upward, according to the accommodations, whether in a ward or in a pri-

vate room, with an extra charge of \$5.00 for dressings and furnishings and for administering anæsthetics. A great number of our medical men availed themselves of this privilege and kept under their own care patients they had before been compelled to refer to some one with a hospital appointment.

In 1893 the Chicago Hospital was organized by seventeen medical men to provide a place where they could give their private patients the nursing and other advantages of a hospital at the usual rates. To assist in paying its expenses they offered these same advantages to other members of the regular profession at a cost of from \$15.00 to \$25.00 per week, according to the room occupied, with an extra charge of \$5.00 for use of the operating-room, but which extra charge was never enforced. This hospital became popular with the profession from the first and its beds were almost always filled.

In 1894 the Englewood Hospital was organized and from the start offered to the general profession the use of its ward beds for \$10.00 per week and of its private rooms for \$15.00, reserving its charity work, etc., for the regular staff. About this time Provident Hospital (colored) offered its facilities to the profession—ward cases \$7.00, private rooms \$9.00 per week, cases of abdominal section \$9.00 in the ward and \$12.00 in private rooms. The example was contagious and to-day there are about a dozen private hospitals in Chicago open to the general medical profession at from \$7.00 per week up, and no medical man whose patient can pay that sum need refer him to a general hospital for operation or treatment.

So popular has the movement been that about a year ago Lakeside Hospital was compelled to add one-third to its capacity. In 1895 Chicago Hospital built a large modern building with three operating-rooms, increasing its number of beds fourfold. Englewood Hospital during February will add to its capacity nearly one-third and during the summer Provident Hospital will build a new and much larger building. What has been the effect? Our general hospitals have been depleted of their patients and from financial stress are compelled to enter into competition with the private hospitals for the patronage of the general medical profession. The Presbyterian Hospital, an adjunct of Rush Medical College, offers its private rooms at \$15.00 per week to any regular physician and he can have entire control of his patient.

Mercy Hospital, which has a contract that runs several years yet to allow no one save a member of the staff appointed by the Northwestern University Medical College to care for a patient there, now offers its private rooms to the profession at from \$15.00 to \$20.00 per week. In fact, so great is their financial stress I am reliably informed that one of the officials recently said that "notwithstanding the contract the devil could put his patients in there if only he paid their board." St. Luke's Hospital (Episcopal) has recently doubled its staff to gain the additional influence in procuring patients, and has recently issued a circular calling attention to its private rooms at from \$12.00 to \$30.00 per week, saying, "Private pay patients will make their own arrangements with such member or members of the attending staff as they may desire." It also directs particular attention to the following:

"By recent action of the medical board and the board of trustees, physicians not officially connected with the hospital may now be permitted to treat their own patients in our private rooms."

The movement has now become so great that the time is close at hand when financial stress will compel Chicago hospitals to open not only their private rooms but also their wards to the regular profession.

What has been done in Chicago may be done in New York or in any large city. If a few of the private

hospitals will open their doors to the general profession and give their patients the care and nursing they receive in general hospitals at the same price, the general hospitals will soon be compelled to open first their private rooms and afterward their wards to the general medical profession.

A. L. CORY, M.D.,
Gynecologist to Englewood Hospital, Surgeon L. S. & M. S. Ry.

4101 STATE STREET, CHICAGO.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The article in last week's MEDICAL RECORD by Dr. Henry S. Stark I read with very great interest, as I am sure every one who is acquainted with hospital matters must do. Dr. Stark treats the matter only from the position of the general practitioner. There is another side to this matter that affects the general public. The admission to the wards of the hospital of the general practitioner and a consequent closer relationship between this class of physicians and the hospital authorities will cause to a great extent a cessation of the pauperizing mentioned by Dr. Stark. Of course it is a matter of public knowledge that many go to hospitals who would not do so if it were known who they were, for they would be as much ashamed to ask medical alms as any other sort.

If then we can have this change in hospital management proposed by Dr. Stark, by a system of coöperation with the Charity Organization Society the treating at hospitals without pay of those abundantly able to pay will be very much lessened. At the dispensaries also blanks should be kept ready for each new patient to fill (or furnish information for another to fill), stating name and address and former medical attendant. Temporary relief should be given without waiting for a reply. A satisfactory response from the family physician should be forthcoming before further medical aid is given, or, if there be no family physician, the Charity Organization Society could and would investigate as to the financial ability of the patient. To ask this organization to investigate all comers would be to ask of them an impossibility, but, lightened as the task would be by the responses of the family physician, this organization could report such cases as were referred to it at a trifling expense.

The pay cases in the hospitals that would result from this system would many times reimburse them. The city would be benefited in that citizens no longer would be made paupers by first receiving medical charity. Few recognize how alarming this matter really is, and how directly the hospitals, by giving free treatment to those well able to pay, are responsible for many of those persons ultimately becoming paupers.

To sum up, then, by this plan the city would be benefited. The hospitals would be benefited. The patients would themselves be benefited in that they are made better citizens. The general body of physicians would be benefited in two ways—the fees which should properly go to the general practitioner would go to him, and there would be engendered a better feeling in the profession.

All this, and no one would be actually hurt. Only the visiting physician and surgeon would be affected and he would not really be harmed. His position would still be what it now is but he would have less work to do gratuitously. W. WASHBURN, M.D.

21 EAST TWENTY-FIRST STREET,
January 5, 1896.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Stark's suggestions are correct and just; they have been followed here for many years. We have the Pius Hospital in charge of the Franciscan

Sisters. It is a private pay hospital, with all the modern improvements. There is no medical or surgical staff connected with it. The sisters receive patients; the patient pays for board, room, and nurse, and has to select and employ his own doctor, and pay for his own medicine. The sisters will not recommend nor favor any doctor. Any patient sent to this hospital is well taken care of. Prescriptions are sent to any drugstore desired by the patient or physician.

If the patient requires an operation the sisters charge \$5.00 for the use of a well-equipped operating-room, and furnish everything except medical assistance and instruments, the surgeon making his own selections. Whether the patient pays the doctor a fee or not is not the sisters' business; all they do is to take care of the doctors' patients.

And then there is the Woman's Medical College Hospital; they have a medical staff and a house surgeon, it is true, but the hospital is open to all. Any physician can send his patient there, rich or poor, and treat him or her himself; the operating-room is at the disposal of any surgeon who wishes to make use of the advantages offered, viz.: For the sum of \$5.00 everything necessary is furnished for a certain operation, including the instruments, ligatures, dressings, etc.; the surgeon selects or brings his own assistants; and not a soul interferes unless requested. The same or similar opportunities are offered at the Baptist Hospital and the Baptist Sanitarium. We hope that all the other hospitals will soon adopt a like plan for their own benefit.

In conclusion I will say that the exclusion of the profession in general seems to me not so much the fault of the directors of a hospital as it is due to the ego of the medical staff connected with the hospital. Our plan as outlined above, works well here and we have no complaint to make.

EDWARD BORCK, M.D.

ST. LOUIS, MO.

BLOOD EXAMINATIONS AND THE DIAGNOSIS OF MALARIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial regarding the value of blood examination as diagnostic of malaria has led me to give experience which may be of interest to some. The East Indian surgeon, Lieutenant-Colonel E. Lawrie, M.B., is one among many who do not believe in the plasmodium of malaria; and the reason of unbelief is, probably, that until the organism has been seen and becomes familiar it is very hard to find in the blood.

Some years ago (1890) in Vienna, I was discussing the matter with my instructors in pathology—Drs. Kolisko and Paltauf, of the medical department of the university. They were very skeptical, said that the plasmodium had never been found in Vienna although it had been eagerly searched for, and were rather inclined to smile at the claims I made in the matter. Paltauf said that to settle the question he would take me to see the next case of malaria he could find, and it would be a test case to decide whether Vienna malaria showed plasmodia in the blood. I assented to the proposition. A long time after that he came to me and said that a colleague of his, a young man who had been sent to Persia by the government on some scientific expedition, had there contracted malaria which had shown itself on his return to Vienna, and that the gentleman was at present suffering from quotidian ague and was under his charge. "Now," he said, "we will take our microscopes and go over and get some of his blood before his chill, which is to be at about one o'clock to-day." I agreed to go, and armed with two great microscopes we broke

into the unhappy man's presence and demanded blood. He was extremely pallid and tremulous and the tips of his fingers were cyanotic, which appearances were probably caused as much by the fear of our intentions as by the malarial poison. I am quite sure he thought that we were as likely to take a quart of blood as a drop, for he handed himself meekly over to us and said, with a heroic air, that he was ready to offer himself upon the altar of science; whereupon we each secured a minute quantity of blood and quickly began the great international microscopic race, in which I felt proud to wear the colors of my country. At the start, Paltauf led off by getting his preparation ready and in place rather ahead of me, and he was confident that if there was anything in that blood he would find it first. But he lost, for in about half a minute I found a beautiful specimen of the intracorpuseular pigmented body, the common form—in other words, won the race by several corpuseular lengths. In a few seconds after Paltauf saw my discovery and what it was like, he had no difficulty in finding many similar ones in his preparation. I took my captive up to the laboratory, where it remained on exhibition for many hours, and a great many assistants and students came up to view the interesting appearance. After that, Nothnagel and Kohler on several occasions demonstrated in their clinical lectures the presence of the organism in the blood of their malarial cases.

It is to be sincerely hoped that no one on reading this narrative will accuse me of vainglory, because there are no microscopists in the world more skilful than the Vienna men in general and Dr. Paltauf in particular, but in this case I had the overwhelming advantage of knowing what the object for which I was searching was like, although I was the merest tyro in the art of handling the microscope.

Many make the mistake of searching with an oil-immersion. This, for obvious reasons, should never be done. The plain lens of moderately high power should be used, and when the object is found it can be fixed under the oil-immersion and studied.

Dr. Paltauf then resurrected a microscopic preparation some twenty or thirty years old, made from the brain of a man who had died comatose from a congestive chill in the Krankenhaus. And there, most beautiful to behold, were the capillaries of the brain filled with the pigmented bodies, exquisitely distinct even after that lapse of time. And this appearance was originally supposed to be simply a deposit of pigment from broken-down corpuscles.

The only contribution in the way of anything new that I can add to the subject can be told in a few words. When I was resident physician at Blockley Hospital, in the obstetric department, a negro woman was admitted suffering from quotidian (?) attacks. Examining her blood, I found after laborious search a very active flagellate organism and one crescent, a rather singular combination. A day or two afterward she gave birth to a baby, which for several days was feverish and unwell. Examining the child's blood on the third day after birth, I found an enormous pigmented body, the particles in most lively motion. Dr. F. W. Talley, of Philadelphia, examined the specimens with me. Under calomel and quinine, both mother and child speedily recovered. But the above observation tends to confirm the belief held by people in malarious regions that the child may suffer with intrauterine malaria, as evidenced by supposed paroxysms of ague in utero.

It is probable from what I narrate, that Lieutenant-Colonel E. Lawrie, M.B., may be neither prejudiced, ignorant, nor incompetent. But his strenuous opposition to the plasmodium of malaria in the teeth of the assertion of Laveran, Osler, and other high authorities would indicate a confidence in himself as against the

world and a reckless tendency to court weighty and unreasonable responsibility, a personal peculiarity that is not altogether unknown, but hitherto has fortunately been rarely chronicled in the annals of medical science.

Had Lieutenant-Colonel E. Lawrie, M.B., simply announced to the world that he had searched in many cases and had not been able to find the organism, his statement would have been admirably succinct and clear, and would have been a most excellent example of extreme honesty and candor. But actually to form an opinion and argue for his belief with only his negative experience as proof shows a tendency to be easily led astray that is, to say the least, mournful and embarrassing.

The principle at the core of Colonel Lawrie's work, however, is exceedingly good, viz., the control of "circular" reasoning, which form of reasoning is being used daily as most excellent logic in many medical matters. A most startling example of it is shown in the diphtheria-bacillus craze.

A diphtheria bacillus called the Klebs-Loeffler bacillus is found, which is said to be characteristic of true diphtheria. But true diphtheria is not unerringly recognizable.

If it is recognizable, why is it that every one has to submit doubtful cases to the bacteriological test, which test, *mirabile dictu*, is held to be conclusive? Is it not plain that the very evidence that is accepted derives its power as reliable evidence from very insufficient sources? In other words, a bacillus that is found in some doubtful cases is used as a logical lever to put many other cases, not a whit more doubtful, off the list of true cases of the disease.

In malaria, however, we have a specific remedy which helps us in our diagnostic reasoning. The cure of malaria by quinine is of as much diagnostic significance as is the cure of syphilis by mercury and the iodides.

When cinchonism is induced the plasmodia diminish and disappear.

But the most ardent believers in the plasmodium do not make absurd claims similar to those of the diphtheria enthusiasts, viz., that the absence of the malarial organism proves that the case is not one of malaria. On the contrary, it may be said, then, either that the protozoa (?) are so scarce that they cannot be found, or that the disease under examination may not be malaria.

S. P. PRESTON, A.B., M.D.

LYNCHBURG, VA., February 12, 1896.

EARLY RISING AND INSANITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Referring to your interesting leader on early rising and insanity, which appeared in your issue of December 28th last, I should like to be permitted to add that Cervantes also observed the connection between the two. Thus he writes in the first chapter of his life of Don Quixote: "The master himself was nigh fifty years of age, of a hale and strong complexion, lean-bodied, and thin-faced—an early riser and a lover of hunting." And again: "In fine he gave himself up so wholly to the reading of romances that a-nights he would pore on until it was day, and a-days he would read on until it was night; and thus by sleeping little and reading much the moisture of his brain was exhausted to that degree that at last he lost the use of his reason."

A recent writer, Sir William Fraser, Bart. (*Hic et Ubique*, 1893, p. 15), also makes some judicious remarks on the subject. Speaking of the great English lexicographer, he says: "It seems strange that Dr.

Johnson, self-accuser as he was apt to be, should not have known his so-called idleness to be absolutely obligatory. He reproaches himself for taking too much sleep; and appears not to have reflected that he owed his vast and vigorous intellect in some degree to the repose which he gave it; such a mind as his must have got out of gear had he not given it frequent and constant rest. The absurd idea that a prolonged sleep indicates a feeble mind is directly the contrary of the truth. An active intellect must require much repose."

Turning to Boswell's "Life of Johnson," we find some interesting medical opinions on sleep. "Johnson observed that 'a man should take a sufficient quantity of sleep, which Dr. Mead says is between seven and nine hours.' I told him that Dr. Cullen said to me that a man should not take more sleep than he can take at once. Johnson: 'This rule, sir, cannot hold in all cases; for many people have their sleep broken by sickness; and surely Cullen would not have a man to get up after having slept but an hour. Such a regimen would soon end in a long sleep.' Dr. Taylor (that is, the Rev. Dr. Taylor) remarked, I think very justly, that 'a man who does not feel an inclination to sleep at the ordinary times, instead of being stronger than other people, must not be well; for a man in health has all the natural inclinations to eat, drink, and sleep in a strong degree.'"

To conclude, the lines on "Early Rising" by one of your American poets, John Godfrey Saxe, are very much to the point:

" 'God bless the man who first invented sleep!
So Sancho Panza said, and so say I;
And bless him also that he didn't keep
His great discovery to himself; nor try
To make it—the lucky fellow might—
A close monopoly by patent right!

" 'Yes—bless the man who first invented sleep
(I really can't avoid the iteration);
But blast the man, with curses loud and deep,
Whate'er the rascal's name, or age, or station,
Who first invented, and went round advising,
'That artificial cut-off—Early Rising!

" 'I like the lad, who, when his father thought
To clip his morning nap by hackneyed phrase
Of vagrant worm by early songster caught,
Cried, 'Served him right!—it's not at all surprising:
The worm was punish'd, sir, for early rising!'"

I remain, sir, yours faithfully,

GEORGE PERNET, B.A., M.R.C.S. Eng., L.R.C.P. Lond.
UPPER GLOSTER PLACE, LONDON, N. W. (ENGLAND).

ANTISEPSIS IN TUBERCULOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The article by Cyrus Edson, M.D., of New York, in a recent issue of the MEDICAL RECORD announcing his discovery of a new cure for consumption naturally suggests a few objections. It is nothing new to say that to saturate the body with an antiseptic fluid would require a quantity which, as Dr. Edson has it, would be "overwhelmingly toxic." The amount of blood in man is about one-thirteenth part of the body weight, which means ten pounds of blood for a person weighing one hundred and twenty pounds, consequently one-half ounce of a germicide would have to be injected into the blood, and this quantity must be maintained in spite of rapid excretion.

Trudeau in 1893 and Cornet succeeded in rendering guinea-pigs partially immune against tubercle infection, the former by antitubercular inoculation, the latter by injection of creosote.

Admit, however, the possibility of surcharging the blood with an antiseptic. Early in the development

of the disease the blood-vessels of the affected centre are destroyed, rendering it impossible for the medicated blood to reach the tuberculous part. An extension of the disease may for a time be prevented, the antiseptic blood stream reaching to the margin of the diseased area. But how destroy the bacilli within the tubercle? They multiply despite all antiseptics, and when there occurs a breaking down of the tuberculous walls an invasion of the bacilli to all parts of the body is the result.

Now is it possible to saturate the body sufficiently to cause instant destruction of the bacilli when released? As the living cells in the body constitute our greatest factor in resisting the attack of these micro-organisms, how will these cells endure the toxic action of the germicide? Admitting that the vitality of the germs would be lowered, would there not be a simultaneous decrease in the vitality of these protecting cells, not alone at the tuberculous lesion but throughout the body?

Pursuing such treatment is in direct opposition to and not assisting nature, as Dr. Edson asserts, and reminds one of the old practice of bleeding a patient who, suffering from fever, requires every spark of vitality to resist the disease.

JOSEPH MUIR, M.D.

34 WEST THIRTY-THIRD STREET.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I was very much interested by Dr. Cyrus Edson's article entitled "A Rational Treatment for Phthisis Pulmonalis, together with Some Notes on a New Remedial Solution," published in the MEDICAL RECORD of February 8th.

Dr. Edson may or may not have invented a valuable new remedy, but I submit that the theory on which his would-be facts are based is fallacious. Because phenol, which can be found in traces in healthy urine, is greatly increased in the same excretion under certain pathological conditions, the doctor concludes that this increase is "one of Nature's many devices to cure the underlying condition—to destroy the germ infection." That is certainly not a very substantial theory. It would be, at least, just as reasonable to conclude that the increased elaboration of phenol in disease is due to faulty metabolism, and that instead of serving a useful purpose it helps to poison the system.

According to Dr. Edson's theory it would be rational to conclude that the presence of sugar is curative in diabetes. There are traces of sugar in normal urine, hence its great increase in diabetes must mean that nature elaborates it as a curative agent against the disease!

F. W. KOEHLER, M.D.

1001 FOURTH AVENUE, LOUISVILLE, KY.

ACETYLENE GAS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your article on acetylene gas in the issue of February 1st, you say that so far as you have learned the only serious objection to it is that it is extremely poisonous. I would add to this its explosive nature. A merchant of our town had manufactured some acetylene, intending to use the light in his store window. He had the gas in the cellar, and one day having occasion to go below for some goods lighted a match to see his way better; and though several feet away from the gas tank, an explosion occurred which shook things up lively. A piece of iron struck our enterprising friend in the face, breaking his nose and causing injuries which nearly proved fatal.

F. G. LEGGE, M.D.

ALLEN, MICH., February 3, 1896.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

GENITO-URINARY SECTION.

W. K. OTIS, M.D., CHAIRMAN.

Suprapubic Cystotomy for Stone.—DR. JAMES R. HAYDEN presented a stone weighing three hundred and sixty grains, removed from the bladder by suprapubic section. The points of interest were the absence of any marked symptoms and the shape of the stone, tapering to two points, which apparently had occupied the vesical opening of the two ureters, although, as the chairman said later, this was hardly probable.

DR. BANGS and DR. ERDMANN recalled cases of large stones, doubtless in the bladder for a considerable period, which had given rise to only very light symptoms until somebody practised careless catheterization and set up severe cystitis.

Double Tuberculous Epididymitis.—DR. IRWIN H. HANCE presented a man, thirty years of age, with double tuberculous epididymitis. There was no family history of tuberculosis, but his wife had had tuberculosis a year and a half or longer. No venereal disease was shown. There had been frequent micturition with irritable bladder for over a year, but the general health was unimpaired; during the last four weeks there had been slight pains over the bladder and dull pain in the right testicle, which was tender; a week later the left testicle was more painful and swollen, with slight hydrocele and enlarged inguinal glands. No very definite signs could be discovered in the chest. There was flocculent deposit in the lower portion of the urine, a large number of pus cells, some coarse epithelium, and half a dozen tubercle bacilli. The tuberculous epididymitis was probably secondary to some undiscovered focus, perhaps in the seminal vesicles or the prostate. It was often difficult to find tubercle bacilli in the urine. To determine their presence inoculation tests might be made on guinea-pigs by injecting fluid from the epididymis or hydrocele if present, but the quantity of hydrocele fluid injected might have to be considerable before giving positive results. Dr. Hance mentioned some cases of tuberculous epididymitis showing improvement by the climate at the Adirondack Sanitarium.

DR. GIBSON raised the question whether a sea voyage was advisable in tuberculosis.

DR. BANGS replied that he had found a high, dry atmosphere best for most patients, but it was well to learn of the patients themselves in what climate they had felt best.

DR. W. K. OTIS had found that his patients did badly in sea air, whether on shore or on water.

DR. HANCE believed that long sea voyages were not advisable, as the patient might be seasick or he might be dissatisfied with his surroundings and wish to be ashore. Mental depression always acted unfavorably. Fully one-half of the patients came back after a long sea voyage in not so good condition.

Castration for Enlarged Prostate.—DR. CHARLES B. KELSEY presented half the prostate removed post mortem six weeks after castration in the case of a man, aged sixty-nine, who had had urinary obstruction, cystitis, etc. He would not have performed castration had there not also been hydrocele and hernia. The man lived six weeks; castration had no ill effects, but did not cause any reduction of the prostatic hypertrophy and in no way relieved urinary retention. The prostate weighed forty-five drachms. Minute microscopical examination showed no atrophic

change induced by castration. So far as he knew the only other case in which castration for prostatic enlargement had been followed later, three weeks, by post-mortem and microscopical examination of the prostate had been reported by Griffith, of England, and in that instance it was stated there was marked atrophy.

Nephrectomy Secondary to Nephrotomy.—DR. EUGENE FULLER reported a case of nephrectomy secondary to nephrotomy, the reasons for making the nephrectomy a secondary operation being those given by Israel. The pus sac was thoroughly drained; the kidney was markedly reduced and could be removed through a smaller incision; plastic lymph was thrown out and reduced the amount of absorption following nephrectomy for pyelitis; the condition of the other kidney could be better studied in its bearing upon the propriety of nephrectomy. The case reported was one in which the urinary and other symptoms had been attributed by several physicians to trouble lower than the kidney. Dr. Fuller made an incision in the loin and reached the kidney, which was of the size of a coconut, let out pus, found a small stone in the pelvis of the organ, inserted two drainage tubes packed with gauze, and at the end of two weeks removed the kidney.

No secreting tissue remained; the organ was three-fourths the normal size and was removed in fourteen minutes through the former incision, although the new adhesions caused a little difficulty. The patient made an excellent recovery and the urine was clear.

Some Acute and Chronic Conditions of the Prostate Gland.—DR. L. BOLTON BANGS devoted the larger part of a paper bearing this title to the subject of etiology. In his opinion sexual excitement and abuse in various forms had a great deal to do with the hyperæmia, the functional derangement, and the later hypertrophy of the prostate. Sexual hyperæmia and irritation was seen in the masturbating youth, the engaged young man, the newly married couple, the docile husband whose æsthetic wife repelled intercourse as carnal, the professed libertine. From conversation with many persons of healthy mind he had arrived at the conclusion that for the average man the sexual act should not take place oftener than once a week. Possibly twice in that period might not be injurious, but greater frequency would leave the blood vessels dilated and the prostate in a state of constant hyperæmia, leading to hypertrophy and in the end to obstruction of the urethra. Among the functional derangements caused by sexual excess or irritation and by urethritis were a sensation of burning in the bladder, anus, or perineum; weakness, feeling of impending emission, sensitiveness to exploration, symptoms relating to urination, mental depression.

The treatment was divided into that relating to acute or subacute conditions of the prostate and the chronic condition known as hypertrophy or overgrowth of the organ. In the former, assuming that the person was rightly married, systematic sexual intercourse rather than abstinence was to be advised. Pains in the feet, back, itching in the scrotum, etc., were relieved by hot sitz baths, rectal injections, local treatment of urethritis and of the prostate. In using solution of nitrate of silver the object should be to obtain its alterative effect, not the cauterizing effect, 1 to 1,000 being strong enough unless there was a history of gonorrhœa. Massage of the prostate might be useful after irritation had subsided. By this was not meant "stripping" the seminal vesicles, a procedure which was beneficial in the condition for which it was indicated.

The man whose bladder habitually contained residual urine was more likely to become infected than another, and the passage of a catheter in such a person was an important surgical procedure. A method of overcoming

retention which had frequently proven successful in his hands and in the hands of his house surgeons was irrigation of the urethra, while the pelvis was elevated, with boric-acid solution, to be repeated in an hour. If it did not succeed use a catheter. Some withdrew all the urine at once, but Dr. Bangs thought it safer to leave some, taking away a little more at each successive sitting. The educated and well-to-do might get along comfortably with the use of the catheter indefinitely, but the ignorant and poor were more likely to require an operation in the form of drainage of the bladder or prostatectomy. Removal of the prostate was still attended by high mortality, twenty to twenty-five per cent. Having listened to Dr. White's presentation of the subject of double castration, he believed there were cases which could be benefited by that measure, and it deserved our consideration. He had been surprised, however, to learn that the death-rate was as high as seven per cent.

In conclusion, he wished to call attention to the view that prostatic hypertrophy was due to senility. He and others had, however, seen it cause urinary retention as early as the fortieth year, and he believed it began during the active period of sexual life, although facts proving this were difficult to arrive at.

DR. SAMUEL ALEXANDER had been much interested in Dr. Bangs' presentation of this subject, but had not been convinced that sexual hyperæmia was an important cause of prostatic enlargement. One reason for doubt was the fact that sexual over-excitement was so common, quite out of proportion to the number of cases of prostatic enlargement seen in later life. He did not question that it had some influence. Regarding castration, he did not think Dr. White's paper justified our offering it to patients without a large question mark. It was a physiological experiment, and it was not unlikely that the benefit reported had been due to diminished hyperæmia or other cause than atrophy of the prostate.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 12, 1896.

THE PRESIDENT, DR. J. C. WILSON, IN THE CHAIR.

Precision in the Technique of Hydrotherapy.—By invitation of the directors DR. SIMON BARUCH, of New York, read a paper on "The Importance of Precision in the Technique of Hydrotherapy." He pointed out that when he made his first plea, seven years ago, for the employment of the Brand bath in the treatment of typhoid fever, not a single voice was raised in his support. A few days later, however, he received an invitation to instruct the medical staff in one of the divisions of Bellevue Hospital in the technique. Encouraged by the gratifying results that have been obtained since that time, Dr. Baruch has been led to employ hydrotherapy not only in acute diseases such as typhoid fever, pneumonia, and the exanthemata, but also in chronic diseases such as tuberculosis, rheumatism, and gout, in which the nutritive tissue-change or hematosis is defective. The virtue of water as a therapeutic agent resides in its flexibility, inasmuch as by a judicious adaptation of temperature, duration, and pressure, it may be applied in conditions of the greatest feebleness and variety.

In the average medical mind the following objections to hydrotherapy at once arise: (1) The difficulty of applying water systematically and with precision, from the lack of facilities and the natural repugnance to water on the part of most persons. (2) The espousal of water as a remedy by empirics and ignorant laymen, who have brought it into disrepute. (3) The utter disregard of exactness of technique. The last is

probably the chief cause of the indifference of the profession, as failure will surely result from inattention to details. It is a too common error to confound all kinds of cold bathing and sponging with the Brand treatment. It has been definitely ascertained that high temperature is not the chief danger to be feared in an attack of typhoid fever. The object of the Brand bath is the support of the nervous system, with a secondary consideration for the temperature. A longer bath at a higher temperature would also reduce the bodily temperature, but it would be lacking in the nervous stimulation. Friction of the body and cold affusion of the head augment the influence of the cold bath, which is appreciable in the improved action of the heart, lungs, and secretory organs. To obtain the ideal result a precise technique must be followed. This consists in beginning the friction baths at 65° F. before the fifth day of the disease and continuing them without fail every three hours night and day when the patient is awake, so long as his temperature reaches 102.5° F. The bathing cannot begin too early and no harm can result should the case prove not to be one of typhoid fever.

The Brand bath may at times serve as a diagnostic guide. Whenever the morning temperature is above 102° F. on the third or fourth day of a febrile disorder and it rises 1° F. or more in the evening, in the absence of a local cause, and a bath at 90° F. with friction for fifteen minutes, repeated in four hours at 80° F. and then 75° F., causes the rectal temperature to fall 2° F. or more, typhoid fever can almost positively be excluded.

In the treatment of pneumonia, and especially the broncho-pneumonia of young children, excellent results have been secured by the use for ten minutes with friction of the tub bath at a temperature of 95° F., gradually reduced to 80° F. during the first bath. Succeeding baths are repeated at intervals of four hours if the temperature reaches 103° F. or more. In the treatment of pneumonia in adults the results from this method and also from the strict Brand bath were unfavorable. The following procedure, however, has proved entirely satisfactory. The patient receives first from ten to twenty grains of calomel, and is carefully sponged with soap and water and dried. Two compresses of three thicknesses of old crash or linen towelling or sheeting are wrung out of water of a temperature of 60° F. and neatly applied to the chest, being covered firmly with a flannel bandage. The application is renewed every hour so long as the temperature ranges between 100° F. and 102° F., and every half-hour if the temperature be higher. Free libations of water are permitted and strychnine is employed hypodermically if the action of the heart is feeble.

The judicious employment of water is also capable of excellent results in the treatment of pulmonary tuberculosis. The object here is the improvement of the nutrition. This is effected by first dilating the superficial cutaneous vessels and thoroughly warming the patient by a dry pack, *i.e.*, enveloping him in long-haired blankets, or by a hot-air bath short of inducing perspiration. Then he is subjected to a circular or needle bath under a pressure of twenty-five pounds at a temperature of 95° F., gradually reduced in the course of one minute to 85° F. and followed by a fan douche under a pressure of twenty pounds at a temperature of 90° F., reduced daily 1° F. If precision in the technique be not observed and the patient is exposed to lower temperatures or subjected to higher pressures at the beginning, the results would be serious and discouraging.

In cases of neurasthenia, of atonic and nervous dyspepsia, and of simple chlorosis, the results obtained with hydrotherapy applied with judgment and skill

in improving the nutrition and hematosiis are striking. A patient with chlorosis may be instructed to stand in a tub containing twelve inches of water at a temperature of 100° F., while an attendant squeezes from a crumpled towel or two bath gloves upon successive parts of water at a temperature of 90° F. or less, according to the reactive capacity of the patient, meanwhile rubbing gently the surface of the body. The patient is then gently dried with a soft linen towel and subsequently rubbed with a crash towel. The temperature of the bath should be reduced 1° or 2° F. daily until 50° F. is reached; then larger quantities of water should be poured over the body by squeezing a large sponge quickly over different parts. Later pitcherfuls or basinfuls may be poured over the body with some force.

In the discussion DR. JAMES TYSON expressed himself as a firm believer in the Brand treatment of typhoid fever, which he contended is the only treatment that should be practised. The objections that have been raised and the difficulties that have been encountered are being gradually removed. The portable tub has made easily possible the employment of the treatment in private practice. In hospital practice the mortality has been reduced to seven per cent. and even less. It would seem that something is gained by the reduction of temperature effected by the bath, though this is not the most important result. The almost total absence of stupor, of delirium, and of other symptoms suggestive of a typhoid condition is a striking feature in cases treated with the cold bath, the effect of which is, as has been said, to make every case of typhoid fever a mild case.

DR. H. A. HARE pointed out that for a long time fever was considered a conservative process, although later it was viewed with concern. It has been experimentally shown that animals inoculated with infective matters have a better chance of recovery when fever develops than under the reverse conditions. It is not perfectly clear in what way fever exerts its beneficent influence. This may possibly have some connection with leucocytosis, as it has been shown clinically that cases of pneumonia and typhoid fever attended with an increase in the number of leucocytes have a more favorable prognosis than those in which such increase fails to take place. It is probable that the good effects resulting from the application of cold in the treatment of pyrexia is not due to the abstraction of heat. With the contraction of the superficial vessels there is an afflux of blood to the interior of the body, with consequent elevation of the deep temperature and activity of the viscera. In this way it is probable that the well-known capacity of the liver to destroy toxic substances is increased.

DR. FENTON B. TURCK, of Chicago, also emphasized the importance of precision in method in every detail in the application of water in the treatment of disease. In this connection must be considered the temperature of the bath and its duration, the object to be accomplished, the individuality of the patient, and his tolerance of the treatment.

DR. J. P. CROZER GRIFFITH expressed confidence in the Brand treatment, although in his service at St. Agnes' the method was modified by making the temperature of the bath not quite so low as that prescribed by Brand, with results nevertheless that were quite satisfactory. He also referred to the use of the hot bath in the treatment of broncho-pneumonia in children.

DR. J. M. ANDERS pointed out that the prejudice against the bath treatment in private practice can often be overcome by instructing the family to add to the water a small quantity of alcohol or of vinegar. In his experience it was often possible to give a graduated cool bath when a genuine cold bath would not

be permitted. While the former might extend over a period of twenty minutes, the latter should not last longer than ten. The prolonged stimulation may lead to exhaustion, especially in cases characterized by weakness of the heart. The cold bath has yielded bad results in the treatment of pneumonia.

DR. THOMAS J. MAYS stated that he had for a long time employed cold in the treatment of pneumonia and had never observed shock result. In this disease he prefers local applications in the form of ice packed around the chest in ordinary ice bags. The good results secured are attributable to an influence upon the nervous system.

DR. WHARTON SINKLER stated that different forms of hydrotherapy must be employed in different forms of neurasthenia and some care must be exercised in the selection of cases. In cases attended with perturbation the cold must not be too intense or the application too protracted.

In closing the discussion DR. BARUCH repeated that the primary object of the cold bath in the treatment of the febrile process is not the reduction of temperature. It was from this point of view that Liebermeister failed for a long time to secure successful results. Prolonged baths at low temperatures with quinine during the night, to keep the temperature down, proved inadequate. Feebleness of heart must be considered a distinct indication rather than a contraindication for cold bathing in typhoid fever. In the most perfect form of heart failure, as in syncope, the first expedient is the use of cold water. In the treatment of scarlet fever it is often useful to immerse the patient quickly in cold water and then to gently dry him. The reaction is shown by the glow that follows. The inadequacy of ice to influence the local process in cases of pneumonia and peritonitis is shown by the observation that after application of ice to the abdomen in case of peritonitis the abdominal walls have after death been found frozen, without, however, any appreciable influence upon the inflammatory process.

Should One Sleep After Eating?—We would not now revert to this oft-discussed question to give any one's theoretical views or personal beliefs in the matter, or to bring forward the familiar argument that because animals sleep just after they have eaten, hence the human animal should do the same. Dr. Schule, of Fribourg (*La Méd. Mod.*, January 15, 1896), has, however, approached the subject from the chemico-experimental side and his results are worthy of record. Having analyzed the stomach's contents in two normal subjects a few hours after meals, some of which were followed by sleep and others not, he finds that sleep has for its constant effect the weakening of the stomach's motility and at the same time there is an increase in the acidity of the gastric juice. On the other hand, simple repose in the horizontal position stimulates the motive function of the stomach but does not increase the acidity of the gastric juice. The conclusion is hence reached that, while one should stretch himself out for a rest in the horizontal decubitus after a hearty meal, he should resist the tempting Morpheus, especially if there be present a dilated state of the stomach or if its juices be hyperacid.

Infant Mortality in Paris.—More than 155,000 children under one year die annually in Paris, the greater number of them owing to neglect on the part of their mothers. The proportion of illegitimate births, which at the beginning of the century was four or five per cent. of all births, is now nearly nine per cent. for France and twenty-eight per cent. for Paris. Among the children of Paris wet nurses the average mortality is seventy-seven per cent.

Therapeutic Hints.

Whooping Cough.—

R Infusion of belladonna-leaves (7½ gr.)
in distilled water fl. ʒ vi.
Antipyrin gr. xv.
Simple syrup fl. ʒ i.
M. A teaspoonful every two hours.

—ESCHLE.

Pneumonia.—1. Digitalis in large doses forms one of the most powerful therapeutic means against pneumonia. 2. It causes a favorable action on the heart, lungs, and blood. 3. In large dose, digitalis shortens the duration of pneumonia and gives an increase of the leucocytes. 4. A dose of one gram of the powdered leaves, and daily doses of four to five grams, are borne without inconvenience. 5. Hydrotherapy (cold water) assists in these conditions the action of the digitalis.—NÆGELI-ÅKERBLÖM.

Hysteria.—It is said that one-tenth of a grain of apomorphia, hypodermically, will break up and thereafter prevent an attack of hysteria.

Coffee in Strangulated Hernia and Intestinal Obstruction.—Guérin gives an account of a number of cases of his own in which the following treatment has been successful: Make an infusion of 250 grams of coffee in twelve cups of boiling water. Administer a cupful every fifteen minutes until eight have been taken, then give the remaining four cupfuls at intervals of half an hour. Four hours will effect a reduction. The coffee may be given per rectum or caffeine by subcutaneous injection when it is impracticable to give by way of the mouth.—*Archives de Médecine*.

New Method of Administering Chloroform.—M. Rosenberg contends that the dangers to both heart and respiration are occasioned reflexly by the irritating action of the chloroform on the terminations of the trigeminus distributed to the mucous membrane of the nose, that the same is true of any other anæsthetic taken through the nose, and that this may be obviated by first anæsthetizing the mucous membrane of the nose by using cocaine which is an antidote to chloroform. Having tried this method in fifty cases he concludes: 1. The commencement of anæsthesia is less disagreeable for the patient who never makes defensive movements. 2. The excitement stage is often wanting and is always slight except in case of alcoholics. 3. During anæsthesia it is very rarely a patient vomits, and if vomiting does occur there is little retching. 4. Upon awakening the patient experiences no disagreeable sensation, and is not haunted by the smell of chloroform or ether. The method pursued is as follows: The patient is directed to blow his nose in order to clear the mucous membrane, then, leaning forward or sitting (never lying), to snuff a centigram of a powder consisting of ten per cent. of cocaine hydrochlorate and some inert substance. Repeat in about three minutes and commence general anæsthesia. If the operation is prolonged repeat chloroform continuously drop by drop.—*Gazette des Hôpitaux, from Berlin, kl. Woch.*

Diphtheritic Conjunctivitis.—Improvement in the local manifestation of the disease, as well as in the general condition, followed so quickly upon the employment of antitoxin that its usefulness must be granted. The serum alone is sufficient to produce resolution and recovery where there is no purulent discharge.—MORAX, *Ann. d'Oculist.*, April, 1895.

Injection of Guaiacol to produce local anæsthesia is found to be as powerful as cocaine and can be used in ten times larger doses. Five minutes are required for

the full effect. Solutions of 1 in 10 and 1 in 20 sterilized olive oil are used, a syringe containing ten or five centigrams. [Its vaso-constrictor action may result in sphacelus.—ED.]—LUCAS CHAMPIONNIÈRE, *Bul. de l'Acad. de Méd.*, July 30, 1895.

Tobacco.—As a general rule there is no need to forbid the use of tobacco in surgical cases, with the exception of those involving the eyes, the abdomen, and the bladder, and most of the affections where the use of tobacco is injurious are just those which cause the patient to dislike it; in fact, in these the disinclination to smoke is one of the first signs that a man is unwell. With certain troubles, such as those of the throat and pharynx, or cases of peritonitis, tobacco should not be used.—JANKAU.

Malaria.—The parasites are present in all forms of the disease, and constitute a diagnostic criterion of unfailing accuracy in uncinchonized subjects. The diagnosis of the malarial fevers can be made with certainty by the blood-examination. An intermittent fever which resists quinine is not of malarial origin.—OSLER.

Carcinoma of Stomach.—A continued persistent absence of free hydrochloric acid is, however, as a sign of carcinoma, of some diagnostic value; but the mere absence of acid without the concomitant symptoms cannot be depended upon to establish the diagnosis.—PEPPER.

Pernicious Anæmia.—In approaching the treatment of a case of pernicious anæmia, you ought always to attempt to ascertain whether the case before you is one of those connected with atrophy of the gastric tubules. In some of these cases the catarrhal symptoms are marked and the power of digestion profoundly reduced; and such cases may properly be called pernicious anæmia of gastric origin.—PEPPER.

Herpes Zoster.—The prognosis of zoster is good, save when the forehead and eyeball are affected. Suppurative panophthalmitis and destruction of the globe sometimes occur in spite of all our efforts to save the organ. Obstinate neuralgias that may plague the patient for years may be left behind; but recovery is perfect, as a rule, when the disease ends.—GOTTHEIL.

Alopecia.—The author, taking the ground that alopecia is a disease of the skin and not of the hair, suggests that the heavy layer of the skin be destroyed by vesication, so that the drugs applied may have a more direct action. Saborourand's method is to apply a liquid which will cause a blister, and then on the next day to make an application to the denuded surface of nitrate of silver. The author has found the treatment efficacious and rapid, but as yet insufficient time has elapsed to be able to judge if there will be relapses, as this is another important feature of the disease.—SABOROURAND.

Uterine Pains.—

R Iodoform 5 gm.
Cocaine 1 "
Oleic acid 4 "
Sterilized vaseline 100 "

The oleic acid is necessary to dissolve the cocaine.—MAYET.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 15, 1896:

	Cases.	Deaths.
Tuberculosis.....	82	120
Typhoid fever.....	7	2
Scarlet fever.....	147	11
Cerebro-spinal meningitis.....	2	5
Measles.....	518	19
Diphtheria.....	271	41
Small-pox.....	0	0

Sterility and Divorce.—There are certain people to whom the integrity of the marriage bond is obnoxious and they are forever seeking to prove that a greater latitude ought to be accorded for evading its indissolubleness. A point upon which great stress has been laid is the alleged injustice of condemning any two people to perpetual conjugal relationship in view of the sterility of the parties to the contract—in other words, they claim that sterility ought to justify a demand in nullity of marriage. There would seem, *prima facie*, to be some ground for this contention, but like so many other social reforms the difficulty lies in the application thereof. First of all it would be necessary to define what constitutes sterility, and, having accomplished this task, a medico-legal question would arise as to which of the conjoints is to be saddled with the responsibility of the procreative failure. Sterility after all is often relative rather than absolute, and a very interesting chapter might be written on the curious incompatibility which exists between particular couples, the peculiarity whereof lies in the fact that subsequent remarriage or an irregular union has proved the soil to be less infertile than was supposed. The subject bristles with difficulties because it would often be alleged for the defence that the disability, if any, was the result of pathological conditions induced by the complainant, an allegation which must, of its nature, be very difficult to disprove. What the reformers hanker after would be an automatic law, in virtue whereof all marriages of so many years' standing not complicated by pregnancy would be *ipso facto* dissolved or dissolvable. From a medical point of view the only legitimate ground of objection would be the fact of one or other of the parties being incapacitated for reproduction by reason of some gross physical abnormality, congenital or acquired, as to the existence of which there could be no dispute—when, for example, the wife turns out to have had her "appendages" removed by some enterprising gynecologist, or the husband belongs to the "undescended" variety of the genus man. Knowledge, as Huxley observed, does not go beyond phenomena, and phenomena in this connection must be taken to mean obvious physical misformation.—*Medical Press*.

Locomotion of Gonococci.—Dr. Moore, of Chili, working in Lassar's laboratory, believes he has discovered that gonococci do move. He has demonstrated preparations which show pus cells filled with gonococci, which have a mobility of their own, independent of any current in the preparation.—*La Méd. Mod.*, December 18, 1895.

Metritis Gonorrhoeica.—Dr. Max Madleuer (*Centralb. für Gynäk.*, December 14, 1895) gives the following *résumé* of his investigations: Neisser's gonococcus is capable of passing from the endometrium into the muscular apparatus of the entire uterus and

there setting up an inflammatory process. This inflammation may reach even to the point of abscess production. This result appears especially to occur in the puerperium. Usually the inflammation remains of moderate intensity. The gonococcus disappears quickly from the myometrium in that it either perishes or wanders farther. By the introduction of the germs into the uterine wall even as far as the serosa infection of the peritoneum from the endometrium with evasion of the tubes is a possibility, and in this way perimetritis in gonorrhoea without implication of the adnexa is explained.

Blennorrhagic Diverticuli and Peri- or Para-Urethral Abscess with Gonococci.—Dr. Batut gives the following as his conclusions (*Archiv. de Méd. et de Pharm. Milit.*, No. 9, 1895): 1. There exist blennorrhagic diverticuli around the meatus, in Tyson's glands, along the canal, in Mery's and Cowper's glands, the latter more studied but less frequent than the preceding. 2. Certain large ducts above the urethra, as it were blind external fistulae, or communicating posteriorly with the bladder by a filiform canal, are supplementary urethras due to an arrest of development in the upper urethra and are not erratic glands of Luschka. These supplementary urethras may be primarily invaded by the gonococcus, the normal urethra remaining intact. 3. The gonococcus may also set up periurethral abscess without connection with the canal or with the annexed glandules of the latter, just as it may provoke an abscess at a distance in the periarticular connective tissue. 4. The treatment of the diverticuli is by actual cauterization according to Diday's method; for Cowperitis, incision and cautery; for periurethral abscess, large incision. 5. Extirpation is the only method of treatment truly surgical in all blennorrhagic inflammation of a supplementary urethra.

Hygiene in the Prussian Army.—According to General Staff Surgeon Dr. von Coler, of Prussia, by improving the hygienic conditions of the army the amount of invaliding has been reduced by forty-two per cent. since 1868 and the mortality by not less than fifty-seven per cent. The lives of two thousand soldiers have been saved by hygienic measures, for the deaths in 1894 were two thousand fewer than they must have been if the rate of mortality had been the same as in 1868.

The Insane in Austria.—The general interest always shown in the care of the insane, and especially the present agitation in the United States as to the best methods of provision for this class of patients, have led to brief inquiry into the conditions prevailing in this great medical centre. It is to be noted that, although the practice is not in accord with the ideals, the best medical thought turns in the same direction as in America, and the realization of present purposes will meet requirements in all respects similar to those demanded in the latter country. Unfortunately statistics of recent date have not been prepared, but it is understood that accommodation in institutions is far short of the actual need. In lower Austria there are five provincial asylums for a population of two million, the largest, in Vienna, having a normal capacity of seven hundred with a census of nine hundred patients. Further provision for the municipal insane is made in the wards of Krafft-Ebing's clinic in the large general hospital, where curative rather than custodial features prevail. The asylum proper, a large central structure, flanked by wings with plain exterior, represents the style of similar American institutions built a half-century ago. Originally in the suburbs, its domain is now so contracted by the encroachments of the city as to seriously in-

terrupt the freedom of patients and the administration of the institution. There is little interior decoration, the massive walls and arches and heavy furniture giving an unpleasantly custodial aspect. With the exception of an occasional piano or billiard table, few resources for the amusement of patients are seen. Tobacco is freely used, the corridors of wards for men being open for smoking. Employment is better provided, facilities being afforded in the gardens and in tailoring, shoemaking, bookbinding, and other trades shops for the industrial class. Patients are compensated for their labor, the money being either placed to their credit or in proper cases forwarded to their families. The administration consists of a medical director and subordinate to him the corps of medical and business officers. The so-called dual plan of management by mutually independent medical and financial departments is here regarded with strong disapproval. Of the medical staff, relieved of all other than professional duties, is exacted close attention to the medical work of the institution. To this fact, in connection perhaps with the scientific atmosphere of the neighboring general hospital, may be attributed the careful study and accurate observation of cases which are the features of all medical work in Vienna. The first assistant physician has gained repute as an instructor and lecturer in the clinic of Professor Wagner, which is conducted in the asylum. In treatment little difference from the methods of the best institutions of the United States exists. Opium in generous doses is largely used for relief of the anxiety and worry in cases of active melancholia. The sheet anchor of treatment in these cases, however, is rest in bed, and this system is carried to a greater extent than is common with us, recumbence being insisted upon until convalescence is well established. There is occasional but infrequent recourse to mechanical restraint. Isolation of excited patients is much more common but is deprecated and excused on the ground of expediency, special small wards for individualization of the turbulent class not having been provided in the plan of the buildings. Trional is a favorite hypnotic. Special investigation during the last eighteen months has been made by researches as to the effect upon insanity of tuberculin. It has been hoped that the induced febrile states might be followed by the favorable mental reaction long observed as the accompaniment of erysipelas, typhoid, and other acute infectious diseases. A preliminary report has been published by Dr. Boeck in a recent issue of the *Jahrbücher für Psychiatrie und Neurologie*, iv., 1 and 2, 1895. In the early experiments a distinct improvement was noted in cases of acute insanity. Simultaneously with the pyrexia thus artificially induced, sometimes of high degree, occurred almost invariable and rapid increase in body weight, improved appetite, and gain in sleep, the last in cases where deficient sleep had been a marked characteristic. Further experiments have been conducted with pyocyanus culture, and later results are soon to be reported. An old-fashioned division of patients into "quiet," "moderately disturbed," and "disturbed" classes is compelled by the arrangement of the wards. This, with other present inconveniences, is expected to be overcome in the near future by removal to a new institution and abandonment of the asylum now in use. The plans for the projected institution contemplate removal from the city and separate structures for different classes of patients. In a hospital building proper with all appurtenances for refinements of treatment will be accommodations for the acute insane. Here are to be concentrated the curative resources of the institution, the most experienced physicians, trained nurses, and all approved hygienic and therapeutic means. Other distinct and remote buildings will be provided for the

chronic cases, with appliances for employment and diversion. Various sites are under consideration and the work of construction is expected to be soon undertaken. The occupation of this new hospital will mark the third and scientific epoch of management of the insane in Austria, whose early period is still recalled by the huge "Narrenthurm" or "Fool's Tower" at the back of the general hospital built by Joseph II. for the insane.—*From our Vienna Correspondent.*

A Statue to Pasteur.—It has been decided to honor Pasteur in the district where his first experiments in vaccinating sheep stricken with anthrax were carried out, says *The Lancet*. These experiments were made at Pouilly-le-Fort in 1881, and in grateful memory of the benefits which accrued to agriculture as the result of these scientific experiments a statue is to be erected to Pasteur at Melun, near Fontainebleau. A committee consisting of members of the agricultural and veterinary societies of the Department of the Seine-et-Marne has been formed for the purpose of receiving subscriptions.
